A more serious example of this is cited by Poole (1987a). Selikoff, Hammond, and Churg (1968) found a statistically significant association between asbestos exposure and lung cancer among cigarette smokers (the risk of death from lung cancer was 90 times as high as that for nonsmokers in the general population), but failed to find this same association among nonsmokers (no deaths were reported in this group during the observation period). The authors, taking into account the low statistical power for detecting this effect, drew no conclusions about the nonsmoking group. Others, however, were less cautious and proceeded to (mis)interpret this negative finding. Hoffman and Wynder (1976) wrote: "We conclude from [this study] that asbestos induces mesothelioma of the pleura and peritoneum, but not by itself [cancer] of the bronchus." Similarly, Cole and Goldman (1975) interpreted the study to mean that "[A]pparently, asbestos will produce lung cancer only in smokers." Poole reports that this finding was eventually summarized in a pamphlet distributed to workers in the asbestos industry: "Studies show that if you don't smoke cigarettes, asbestos does not increase your risk of lung cancer." Poole used the data reported in the original study to compute confidence intervals for the risk of cancer associated with asbestos exposure for the nonsmokers, and found the odds ratio to fall in the range of zero to 46.1.

We have shown that power for many studies is low, which leads to nonsignificant results even when treatments are actually effective. And, we have shown that the nonsignificant results are often taken as evidence that the treatment is not effective. Either of these two issues would be problematic by itself, and together these items seriously impede research in psychology.

Schmidt (1996) outlines the impact of this practice on research and policy: an idea is proposed (school integration will result in better test scores for African-American children). A number of studies are run. All of the studies show that scores are increased and the magnitude of the increase is consistent from one study to the next, but the sample sizes are small and, in some of the studies, not significant. Researchers report that the evidence is "conflicting." A series of studies are funded to determine why the integration had a positive effect in some studies but not others (is it the teacher's attitude? Is it the students' socioeconomic status; is it the students' age?), entirely missing the point that the effect was actually consistent from one study to the next. No pattern can be found (since none exists). Eventually, researchers decide that the issue cannot be understood. A promising idea is lost, and a perception builds that research is not to be trusted. A similar point is made by Meehl (1978, 1990).

Rossi (1997) gives an example of this same phenomenon from the field of memory research. The issue of whether or not researchers could demonstrate the spontaneous recovery of previously extinguished associations had a bearing on a number of important learning theories, and some 40 studies on the topic were published between 1948 and 1969. Evidence of the effect (i.e., significant findings) was obtained in only about half the studies which led most texts and reviews to conclude that the effect was ephemeral and "the issue was not so much resolved as it was abandoned" (page 179). Recently, Rossi returned to these studies and found that the average effect size (d) for the studies was 0.39. If we assume that this is the population effect size then, given the sample size in the various studies, the mean power for these studies would have been slightly under 50%. On this basis we would expect about half the studies to yield a significant effect, which is exactly what happened.

It seems unlikely that these errors of interpretation will change as long as researchers continue to work under the current system of significance testing. These types of problems have continued despite educational efforts such as those of Cohen (1962, 1990). They have continued despite the development of simple techniques for computing power, including rule-of-thumb tables (Cohen, 1988; Kraemer & Thiemann, 1987) and computer programs (Borenstein & Cohen, 1988; Borenstein et al., 1990, 1992, 1997; Goldstein, 1989; Rothstein et al., 1990). They have continued despite research that has addressed the kinds of thought processes on the part of researchers that appears to drive these kinds of errors (Tversky & Kahneman, 1971). There are many researchers who are very cognizant of power issues and insist that their studies be properly powered. Most large-scale and multicenter studies are also designed to ensure adequate power for important tests. In this sense, there has been some very substantial progress since the late

1960s. Still, it is clear from Sedlmeier and Gigerenzer, and Rossi, that low power continues to be a problem.

3.14.4.5 Summary

Significance tests are not the appropriate vehicle for the vast majority of psychological research, both because they are inherently inappropriate for this role and additionally because they foster mistakes of interpretation. Specifically:

(i) Significance tests focus attention on statistical significance (whether or not we can reject the nil) rather than clinical significance (which is the question of interest). The test can tell us about the direction of the effect, but in virtually all cases we want also to address the size of the effect.

(ii) There is a general perception that significance tests allow us to distinguish between effects that are "real" and those that are not. In fact, though, virtually all effects we test are nonzero, so the only question resolved by the significance test is whether or not we used a large enough sample.

(iii) The significance test yields *p*-values that lend themselves to misinterpretation. A significant *p*-value is assumed to reflect a clinically important effect, but it may not. A nonsignificant *p*-value is taken to reflect a zero effect, but it does not. These problems are compounded when a series of studies are seen as yielding "conflicting results" for one population, or are seen as evidence that the effect exists in one population but not another.

3.14.5 FOCUSED SIGNIFICANCE TESTS—A DIGRESSION

To this point we have used the term significance test to refer to the null hypothesis of no effect. Overwhelmingly, this is the manner in which statistical tests are applied in the literature. For example, the null hypothesis being tested is that the mean in two groups is identical (i.e., the intervention had no effect), or the response rates in two groups are identical, or the correlation between two variables is zero.

In fact, though, we can adopt a more focused approach by formulating and testing a hypothesis that predicts the magnitude of an effect. This would be appropriate if a theory had developed to the point that questions of effect size would bear on the validity of the theory. It would also be appropriate if we were working with a prospective treatment and the question of interest was whether or not the treatment was clinically useful.

For example, assume that we are planning to test a new drug as a maintenance medication for schizophrenic patients. The drug is known to increase the level of negative symptoms slightly, but would nevertheless be considered useful if it increased the response rate (defined by control of positive symptoms) by 20 percentage points. The hypothesis to be tested is not "Does it increase the response rate at all" but rather "Does it increase the response rate by 20 points *or more*."

The same logic can be extended to a test of means. Assume, for example, that we want to evaluate a new teaching strategy that is expected to yield an improvement in SAT scores. The strategy will be expensive to implement, and a decision is made that it would be adopted on a wide scale only if it increased the mean score by at least 50 points. The hypothesis to be tested is obvious.

The idea of using significance testing in this way is not new. In the psychological literature the null hypothesis tested is almost invariably the null hypothesis of no effect and it is commonly assumed that the word "null" in "null hypothesis" refers to the size of the effect. In fact, though, it is a reference to the hypothesis to be tested, or "nullified" (Cohen, 1997). While the hypothesis to be nullified is usually the hypothesis that two response rates are identical it could also be the hypothesis that, for example, the response rates differ by 20 percentage points. To avoid confusion, Cohen suggests that the term "null hypothesis" be used to refer to any hypothesis to be tested, while the term "nil hypothesis" be used to refer to the null hypothesis of no effect.

Similarly, in the clinical literature the term "significance test" is almost invariably used to refer to a test of the nil hypothesis, but it can refer to any null hypothesis. Cohen suggests that the term "significance test" be used to refer to a test of the nil, while the term "hypothesis test" be used to refer to other tests (such as the 20 point difference). These conventions will be followed here to avoid confusion. The reader should note, however, that these terms are used interchangeably elsewhere.

The use of hypothesis testing rather than significance testing would provide some obvious benefits. For one thing, it would force researchers to think about the meaning of the null hypothesis. Earlier, the example of researchers testing the null hypothesis that a reliability coefficient is zero was cited. With a focused test the researcher could test the hypothesis that the reliability was significantly better than, for example, 0.80. If these kinds of tests were in common use, researchers would have an incentive to formulate the hypotheses more clearly. Additionally, in those cases where the null hypothesis was rejected, one could assert that the effect size fell in a clinically important range ("the relapse rate is reduced by at least 20%").

However, many of the problems described for the use of significance tests with the nil hypothesis would apply also to the use of hypothesis tests for other null hypotheses.

First, the problems in logic that were identified for significance tests apply also, albeit in modified form, to hypothesis tests. It was argued earlier that the significance test addresses the question of whether or not the effect is precisely nil, which is of little import. Similarly, the focused hypothesis test might address the question of whether or not the effect is precisely 20 points. A 20-point difference might be of more interest than a nil effect but is still an arbitrary value. In practice, what we would like to do is to get a feel for the size of the effect as being trivial, or moderate, or substantial, rather than to rule out any specific value. Similarly, it was argued earlier that the nil hypothesis was rarely true, and that with a large enough sample it would almost always be disproved. Similarly, the null hypothesis that the rate difference is *precisely* 20 points is virtually certain to be false and with a large enough sample will almost always be rejected. Under the system of hypothesis testing, with a large enough sample, an observed rate difference of 21 points, or even 20.1 points, will require us to reject the null of 20 points. Of course, this is not the intention in running the test, but it serves as a stark example of why the test is not the appropriate vehicle for this kind of application.

Second, the mistakes of interpretation that were identified for significance tests apply, again in modified form, to focused hypothesis tests. One problem with the significance test is that researchers use *p*-values (improperly) as surrogates for effect size indices. A *p*-value of 0.05 was assumed to reflect a modest effect and a *p*-value of 0.01 was assumed to reflect a strong effect. While the focused hypothesis test does introduce the concept of effect size (a 20-point effect in this example) the key index continues to be the *p*-value. A *p*-value of 0.05 is likely to be seen as reflecting a modest departure from 20 points, and a *p*-value of 0.01 as reflecting a substantial departure from 20 points. Similarly, the absence of significance has traditionally been mistaken as evidence that the effect is zero. With the focused hypothesis test it would be mistaken as evidence that the effect is precisely 20 points.

Additionally, if a move was made to focused hypothesis tests, low power would become even more of a problem than it is now. For example, with a sample of 70 per group using a 50-point difference as the effect size (and $SD = 100$), power to show that one educational method is superior to another is 84%. With the same assumptions, power to show that it is superior by at least 20 points is only 42%. Logically, in fact, we might want to use 50 points as the effect size and also test the hypothesis that the effect is 50 points. When the effect size and the effect being tested are identical to each other, then no sample size will yield power greater than alpha (e.g., 5%).

In sum, the adoption of hypothesis tests would be appropriate for some studies but would not address the key problems outlined above for significance tests, and would additionally introduce some new problems. In any event, the possibility of working with hypothesis tests rather than significance tests is something of an academic point, since the field has bypassed this approach in favor of a more comprehensive approach—the report of effect size with confidence intervals, and it is to this approach that we turn now.

3.14.6 EFFECT SIZE AND CONFIDENCE INTERVALS

For the reasons outlined above researchers and journals are now moving away from significance tests and toward a focus on effect size estimation. Rather than report that an effect is (or is not) significantly different from zero, we report the size of the effect, and specify additionally a confidence interval, the range of treatment effects in the population that are likely to have given rise to the observed data.

In the example cited earlier, assume that we had completed the study and obtained response rates of 30% on drug A vs. 50% for drug B, with a sample size of 100 patients per group. We would report that drug B increased the response rate by 20 percentage points, with a 95% confidence interval of 7–33. The effect size observed in the sample (a rate difference of 20 points) is our best guess about the size of the effect in the population. The confidence interval (seven points to 33 points) reflects the likely upper and lower bounds of the effect in the population (Altman, Gore, Gardner, & Pocock, 1983; Borenstein, 1994a, 1994b; Gardner & Altman, 1986, 1989a, 1989b; Morgan, 1989; Simon, 1986, 1987).

3.14.6.1 The Key Advantage of this Approach

If the key problem with significance tests is that they address the wrong question, then the key advantage of effect size estimation is that it addresses the right question. Working with significance tests we defined an effect and asked whether or not that effect was probably true. It was problematic that the effect was typically of little interest (the nil effect) or selected arbitrarily (the focused hypothesis test). Working with effect size and confidence intervals, rather than report on what the effect is not we report on what the effect is. By doing so we focus on the question of interest. Additionally, we bypass the need to specify an arbitrary null hypothesis.

The effect size with its corresponding confidence interval provides three key pieces of information:

(i) An estimate of effect size that is separate and distinct from the precision of this estimate. Because this is a pure measure of effect, it focuses our attention on the substantive impact. For example, the treatment increases the response rate by 25 percentage points.

(ii) A value for the lower bound of this value in the population (for a given confidence level). With the traditional test we know only that the response rate is increased by some amount exceeding zero. By contrast, with the confidence interval we may be able to report that it is increased by at least 20 percentage points.

(iii) A value for the upper bound of this value in the population. The traditional test provides no estimate at all of the upper bound. By contrast, with the confidence interval we might report that the upper bound for the treatment's impact is 10 percentage points (in which case we know that the impact is of limited substantive value) or that the upper bound is 50 percentage points.

3.14.6.2 Effect Size and Confidence Intervals can be Computed for Any Type of Study

Any study that may be used to compute a *p*-value may also be used to generate an effect size with confidence intervals. This follows from the fact that the *p*-value includes both components (the effect size and the precision). The *p*-value combines the two to yield a single value, but each value can be presented separately. As was the case with significance tests, the exact form of the report will vary with the nature of the data, but the differences are minor.

For studies that focus on the mean difference between groups a natural index of effect is the mean difference itself (either in the original metric, such as SAT points, or standardized to a common metric with a standard deviation of 1.0). For studies that focus on the proportion of cases responding to a treatment, one index of effect is the rate difference, that is, the difference in the proportion responding in either group. Other indices, common in medicine and epidemiology, are the relative risk and the odds ratio, either of which is often presented in log units. For studies that deal with correlations, the correlation itself serves as an index of effect size. For studies that focus on time to an event, or survival, the effect size reported is often the hazard ratio, that is, the relative risk per unit time in one group vs. the other. Computational details for any of these computations are readily available (see, for example, Harris & Albert, 1991; Kleinbaum, Kupper, & Morgenstein, 1982; Lawless, 1982; Rosner, 1990; Selvin, 1991). The goal here is to point out that these exist, and that the effect size can be presented for any type of study.

The effect size is reported with a corresponding confidence interval. The computation of confidence intervals is always some variation on the theme

Lower Limit = Observed effect minus
(Standard Error* 1.96)
Upper Limit = Observed effect plus
(Standard Error* 1.96)

At the core of either equation is the observed effect, about which the confidence interval is constructed. The lower and upper limits represent the lower and upper bounds for the effect size in the population from which the sample was drawn. Computation of confidence intervals for proportions, correlations, or survival times is more complicated than suggested by this summary, and is discussed in more detail below. These computational details aside, the formula shown here offers a straightforward conceptual overview.

3.14.6.3 Factors Affecting the Confidence Interval Width

The width of the confidence interval is based on two factors. The first of these is the sample-to-sample dispersion of the effect size: The higher the dispersion within a sample, and/or the lower the sample size, the more the effect size will vary from one sample to the next. When working with means the dispersion within a sample is indexed by the standard deviation of the scores. Intuitively, if working with a select group of students and the SAT scores cluster in the range of 600–750, sample-to-sample dispersion will be modest. By contrast, if we are working with a broader population, in which the scores cover the full range of 200–800, sample-to-sample dispersion will be wider. The impact of sample size on the standard error of the effect size is also intuitive. If the sample size is small the group mean might be affected substantially by a few outliers. By contrast, if the sample size is large the impact of outliers will be dissipated. It should be noted that when working with proportions or correlations, the first of these elements, the within-sample dispersion, is a function of the index itself. In the case of proportions, when the population proportion is close to 50% the standard deviation is relatively high, and it declines as the proportions approach either zero or unity. Intuitively, one can imagine that samples drawn from a population where the proportion of responders is 99% will yield values close to 99%—it would be difficult to draw many nonresponders since they do exist. By contrast, if the proportion of responders is 50% it would not be hard to draw one sample with a 40% response rate and another with a 60% response rate. Similarly, for correlations, the standard deviation is highest when the correlation is zero, and it declines as the correlation approaches minus one or plus one.

The second factor controlling the width of the confidence interval is the level of confidence desired. For example, one could choose to present the effect size plus/minus one standard error. In approximately 68% of all studies where the confidence intervals are reported in this manner, the interval will include the population effect size. One could also choose to present the effect size ± 1.96 standard errors (assume for this example that the variance is known). On the normal curve, 95% of all observations will fall inside the interval of -1.96 to $+1.96$. Therefore, if the effect size is presented as ± 1.96 standard error units, over an infinite number of studies 95% of the intervals will include the population effect.

The researcher may elect to compute two-tailed or one-tailed bounds for the confidence interval. A two-tailed confidence interval extends from some finite value below the observed effect to another finite value above the observed effect. A one-tailed confidence interval extends from minus infinity to some value above the observed effect, or from some value below the observed effect to plus infinity (the term "interval" is a misnomer in the one-tailed case but is used to maintain readability).

3.14.6.4 Information Conveyed by the Effect Size and Confidence Interval

Figure 5 shows the results of six fictional studies. For each study, the effect (the difference in response rates between placebo and drug) is depicted as a vertical line, bounded on either side by the 95% confidence interval. A solid line from the top to the bottom of the graph marks the null effect of no difference. An effect to the left of this line indicates that the drug group was inferior to placebo, while an effect to the right indicates that the drug group was superior. The studies with narrow confidence intervals are based on a sample of 700 patients per group. Those with wide confidence intervals are based on a sample of between 10 and 15 patients per group. All examples assume that the response rate on placebo is 30%. We can visualize a hierarchy of possible study results, some of which are depicted on this schematic.

Study A: Zero difference (-30 to $+30$). We cannot rule out the possibility that the effect is nil. Nor, however, can we rule out the possibility that the effect is large enough to be clinically useful or clinically harmful.

Study B: Zero difference (-4 to $+4$). We cannot rule out the possibility that the effect is nil. More to the point, however, it is clear that the effect is trivial, at best.

Study C: Twenty-five point difference (-10 to $+54$). The effect size in the sample (and our best estimate of the population effect) is 25 points. We cannot rule out the possibility that the effect is nil (nor can we rule out the possibility that it is quite potent).

Study D: Five-point difference (1–9). The effect is probably not nil. More to the point, however, we can assert with a high level of certainty that the effect is not clinically important (at best, a nine-point advantage in favor of the drug).

Study E: 40-point difference (10–63). The effect is probably not nil. The possible magnitude of the effect ranges from small to extremely potent (the interval is intentionally asymmetric).

Study F: 40-point difference (36–44). The drug is quite potent. The likely range of effects falls entirely within the "very potent" range.

3.14.7 THE RELATIONSHIP BETWEEN SIGNIFICANCE TESTING AND EFFECT SIZE ESTIMATION

The formulas for significance tests and for confidence intervals are mathematically congruent. The standard error of the effect size in confidence intervals is identical to the standard error used in significance testing. The confidence level used for confidence intervals can be complementary to the significance level used in significance tests (with the 95% confidence level corresponding to alpha of 5%).

Given the correspondence between the two methods, any significance test of the form "the difference is zero" and tested with alpha of 0.05 may also be tested by computing the 95% confidence interval and determining whether or

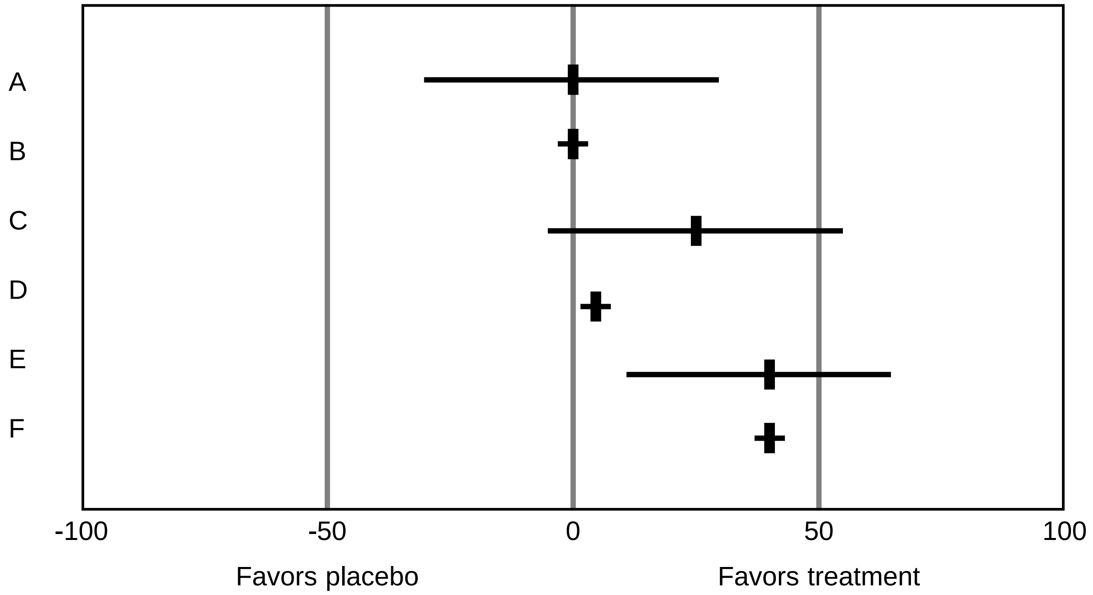

Figure 5 Data for six fictional studies. The effect size for each study is depicted by a vertical line bounded by the corresponding 95% confidence interval. The effect size highlights the magnitude of the effect while the interval width provides information about the precision with which the effect is estimated. This schematic also provides information about the significance test—if the 95% confidence interval excludes zero, the study is significant at the 0.05 level.

not this interval includes zero. More generally, any hypothesis test of the form "the difference is 20 points" and tested with alpha of 0.05 may also be tested by computing the 95% confidence interval and determining whether or not the difference includes 20 points. If the confidence interval includes the null, then we do not reject the possibility that the true effect is the null. If the confidence interval does not include the null, then we conclude that the effect is (probably) not the null. The same holds true, of course, for a significance test with alpha set at 0.01, and a report of the 99% confidence interval.

When we report a confidence interval and then focus on the question of whether or not the interval includes zero, the distinction between confidence intervals and significance tests is one of format rather than substance. However, as suggested by Figure 6, this shift in format is critically important. Working within the traditional framework of significance testing (shown by the columns in this figure) the key distinction is between studies A, B, C (nonsignificant) on the one hand, as opposed to D, E, F (significant) on the other. By contrast, working within the framework of effect size estimation (shown by the rows) we would group studies B and D (not clinically important), then A, C, E (possibly clinically important), while study F (clinically important) would be classified by itself. (A 20-point difference in response rates would be clinically important in the context of this study.)

3.14.7.1 Confidence Intervals as a Surrogate for the Significance Test

Mathematically, then, confidence intervals can serve as a surrogate for the significance test. Should they be used in this way? Researchers have staked out three positions:

(i) Confidence intervals should be used only as a surrogate for the significance test. Otherwise the results are entirely subjective, and we have no basis to make a decision about whether or not the treatment is effective.

(ii) Confidence intervals can serve as a surrogate for the significance test but they can also stand on their own. Some studies will serve best if used to provide an estimate of effect size, accompanied by an estimate of precision. Others would additionally take note of whether or not the confidence interval included specific values.

(iii) Confidence intervals should never serve as a surrogate for the significance test. The significance test has no role in psychological research, and any vestige of the significance test should be removed.

There is a substantial literature developing on these points of view. In general, the debate in the medical literature is between the first two options while the debate in the psychological literature is between the first and the third. The rationale for each of the positions is outlined here.

		Statistically significant	
		No	Yes
Clinically important	No	B	D
	Possibly	A,C	E
	Yes		F

Figure 6 Effect size estimation vs. significance testing. The columns correspond to significance tests—Studies A, B, C are not significant while studies D, E, F are significant. The rows correspond to effect size estimation—Studies B and D show that the treatment is not clinically important, studies A, C, E show that the treatment may be clinically important, and study F shows that the treatment is clinically important.

3.14.7.1.1 Confidence intervals should serve only as a surrogate for the significance test

Some researchers have taken the position that the basic idea of significance testing is a good one, and that the problems outlined above stem from the misuse of these tests rather than from any flaw inherent in the method. They argue that it is critical to retain the logic of the significance test since the researcher and the reader need to make a decision at the end of the study about whether or not the treatment effect was probably "real." By using confidence intervals as a surrogate for the significance test these decision rules are maintained while gaining the following critical advantages over the traditional significance test.

First, attention is focused on the magnitude of the treatment effect. By doing so the tendency is avoided to press the *p*-value into service as an indicator of effect size. A rate difference of five percentage points is seen as being a small effect (in most contexts), even if the sample is so large that the confidence interval does not include zero (and the test is statistically significant). By the same logic an effect of 50 percentage points is large, even if the sample size is so small that the confidence interval does include zero (and the test is not statistically significant).

Second, unambiguous information is provided about the precision of the effect. An effect reported with a precision of ±5 percentage points is definitive—the effect is known to be useless if small, or is known to be useful if large. An effect reported with a precision of ±30 percentage points is likely to leave open the question of clinical utility, but this point will be obvious to the researcher and the reader. Mistakes of interpretation will be less likely than they are with significance tests.

At the same time, this approach preserves the protective mechanisms that are incorporated in the significance test. Specifically, if the confidence interval excludes zero then it is assumed that the effect is not nil; if it includes zero then it is acknowledged that the true effect may in fact be zero (see, for example, Chow, 1988, 1989; Walker, 1986a, 1986b).

3.14.7.1.2 Confidence intervals can optionally be used as a surrogate for the significance test

Others have taken the position that confidence intervals can be used as a surrogate for the significance test, but that it is not necessary to focus on significance when interpreting the results. In the running example one could articulate a series of goals, including the following:

(i) We would like to be certain (where "certain" corresponds to a given level of certainty) that the treatment is not actually harmful.

(ii) We would like to be certain that the treatment effect exceeds zero.

(iii) We would like to be certain that the treatment effect is large enough to be clinically important.

As suggested by Figure 5, the 95% confidence interval might or might not exclude effects that are clinically harmful, that are zero, or that are clinically trivial. More generally, the effect size and confidence intervals might allow us to draw a conclusion about some of these points but not others. Or, they might allow us to answer some questions with one level of certainty, and others at another level of certainty.

In fact, rather than focus on the issue of whether or not the interval includes any single value we can consider the full range of population parameters that are consistent with the study results, recognizing the fact that those falling closer to the observed effect are more probable than those closer to the extremes. This approach was suggested by Birnbaum, (1961). More recently, it has been popularized by Miettenan and by Poole (1987a) who suggests that this is displayed most effectively as a graph of confidence interval by confidence level (see also Foster & Sullivan, 1987; Poole, 1987b, 1987c; Sheehe, 1993; Smith & Bates, 1993; Sullivan & Foster, 1990).

In the running example, assume that 20 patients were followed under each treatment condition and the proportion responding was 25% in one treatment group as compared with 50% in the other. The continuous confidence interval for this data is shown in Figure 7. This graph highlights the fact that the most likely impact of the new treatment mode is to increase the response rate by about 25 percentage points. The 60% confidence interval includes a benefit of between 12 and 37 percentage points for the new treatment; the 80% confidence interval extends from five percentage points to 42 percentage points; the 90% confidence interval extends from zero to 46 percentage points; and the 95% confidence interval extends from minus five (a five-point advantage for the standard treatment) to plus 49 (a 49 percentage point advantage for the new treatment).

While it might seem at first glance that this approach introduces an element of subjectivity into the analysis, the fact is that any test of significance involves an element of subjectivity since the decision to set alpha at a particular level is a subjective one, based (at least in theory) on the researcher's need to balance type-I error against type-II error. Additionally, the decision to focus on whether or not the interval includes the nil effect, rather than (say) an effect of five points or 10 points, is also arbitrary. Therefore, the use of confidence intervals in the manner being discussed here, rather than introducing an element of subjectivity into the analysis, merely shifts the subjectivity that is already there from the researcher and on to the reader (Fleiss, 1986a, 1986b; Thompson, 1987a, 1987b, 1987c, 1987d. See also Cohen, 1962; Derouen, 1987; Lachenbruch et al., 1987; Rosnow & Rosenthal, 1989, Rothman, 1986b; Savitz, 1987).

Perhaps more to the point, the reader may not feel a need to frame the answer as a dichotomy, and to conclude that the treatment does (or does not) have any impact on recurrence rates. Rather, the take-home message might be the more comprehensive picture, that is, (in Figure 7 and introducing subjective judgments) "the 40% confidence interval falls entirely in the range of substantial effects; the 80% interval falls in the range of substantial or moderate effects; and the 95% interval includes effects that are trivial" with the entire gamut of possibilities being factored into a decision about the utility of this treatment (see also Burnand, Kernan & Feinstein, 1990; Poole, 1987a, 1987b, 1987c; Rothman, 1986a, p. 119; Walker, 1986a, 1986b; Walter, 1991).

3.14.7.1.3 Confidence intervals should never be used as a surrogate for the significance test

Others have taken the position that even if the abuse associated with the significance test could be avoided, there is a fatal flaw inherent in this approach. The argument cited above in favor of the first position is also the key argument cited for this position: "If we use confidence intervals as surrogates for the significance test, then we retain the basic protective mechanisms of the significance test. Specifically, if the confidence interval excludes zero then we assume that the effect is not nil; if it includes zero then we explicitly acknowledge that the true effect may in fact be zero." Proponents of the third position would add "And therein lies the problem."

It was argued earlier that the null hypothesis is of little interest. If this is true, then when reporting an effect size we should care about the precision of the estimate, but not about whether or not the confidence interval (CI) includes zero. Put another way, an effect of 30 points with CI of 20–40 is informative; with CI of 10–50 is less informative; with CI of 0–60 is less informative, still. But there is no reason that we should be more concerned about "ruling out zero" than about "ruling out" a five-point effect or a 10-point effect. Knowing that the effect is probably not zero does not tell us that the effect is probably clinically important.

Similarly, it was argued that significance tests are misleading since they allow us to confuse effect size with precision. Studies meet the criterion for significance in part because the sample size is large; studies fail to meet the criterion for significance in part because the sample size is not large enough. By exactly the same logic, if the confidence interval includes zero it is in part because the sample size is too small. If the key issue being addressed by the significance test is whether or not there was a large enough sample, then it makes no sense to perform a significance test, in any format. To do so is to propagate and codify exactly the same error that attempts are being made to avoid (see Schmidt, 1992; Schmidt & Hunter, 1996, 1997).

3.14.7.2 Should the Significance Test be Banned?

In 1998 the significance test continues to serve as the *de facto* standard of proof in most research

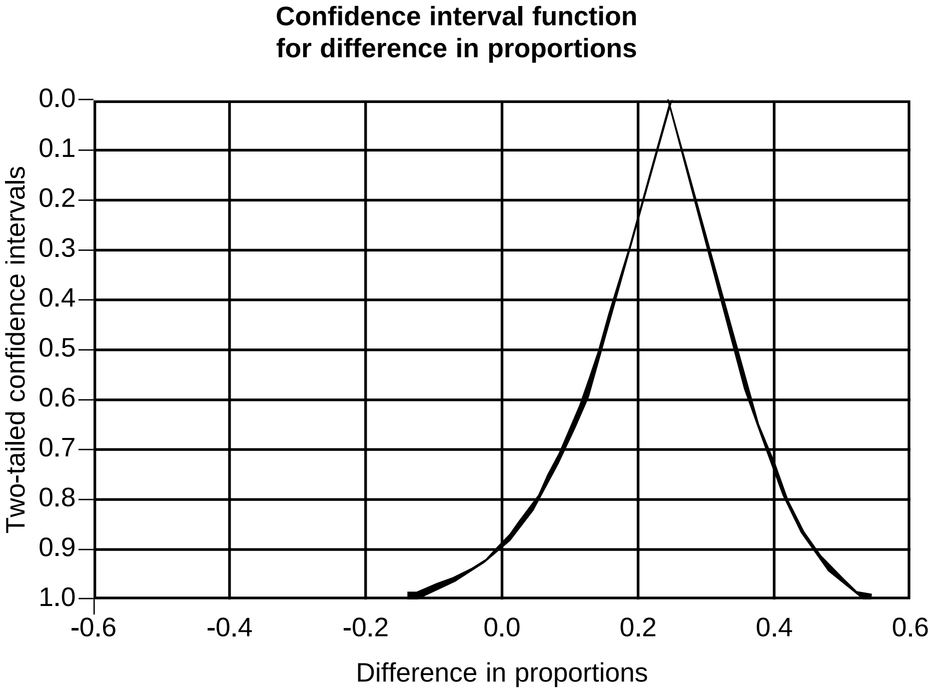

Figure 7 Continuous confidence intervals. Rather than focus on whether or not we can exclude a specific effect size with an arbitrary level of confidence, we can consider the full range of population parameters that are consistent with the study results, recognizing that those falling closer to the observed effect are more probable than those falling closer to the extremes.

studies. As a practical matter, the grant applicant who proposes to skip the significance test is not likely to be taken seriously by the funding agency; drug manufacturers are not likely to submit studies for FDA approval without data on statistical significance; and papers submitted for publication without tests of significance will face a serious obstacle in most journals. In the context of the three positions outlined above, the current state is somewhere prior to the first position. Nevertheless, recent debate has focused on the proposition that the significance test should be banned, which falls at or beyond the third position.

The most vocal proponents in favor of a ban are Schmidt and Hunter (1997) who attack the null hypothesis test on three fronts. First, they note that the null hypothesis is almost always false. Rather than thinking of studies as "significant" or "not significant" we would do well to think of them as "correct" and "incorrect." As long as researchers are permitted to report significance tests, type-II error will continue to run rampant in psychological research. Second, they argue that the role of the single study should be to accumulate data which can later be incorporated in a meta-analysis, and so there is no need to perform a significance test for the single study. As long as significance tests are permitted, the significant studies will be accepted for publication at a higher rate than non-significant studies, which will introduce a bias into the research literature and impair ability to conduct a meta-analysis at a later point. Finally, they contend that the significance test serves no useful function at all. In support of this latter point they proposed a ban on significance tests and then systematically collected objections to this proposal. They summarize these objections by reporting that "Each of these objections is intuitively appealing and plausible but is easily shown to be logically and intellectually bankrupt" (p. 37). Some of the objections to a ban follow, together with comments.

Some have taken issue with the contention that the nil hypothesis is always false. For example, if using a randomized trial to test an entirely new class of drug that actually has zero effect, then the null hypothesis would be true. This is a valid point but largely irrelevant, since it applies to only a trivial number of studies.

Some have argued that significance tests assure objectivity. In fact, one could argue that the hypothesis test is not objective since the selection of a criterion alpha, and also the selection of a specific null to be tested, are made subjectively. Even if one accepts the idea that confidence intervals are less objective, the fact remains that this objectivity leads to ubiquitous errors of interpretation. To paraphrase Tukey, "Be approximately right rather than exactly wrong."

Others have taken issue with Schmidt and Hunter's contention that a single study cannot provide definitive evidence to support or refute a theory. Abelson, for example, cites the classic Festinger experiment, which raised questions about the prevailing theory and set the stage for the studies that followed. (In this study one theory predicted that one group would score higher and the competing theory predicted that the second group would score higher. Ratings were conducted on an arbitrary scale, and the only issue to be resolved was the direction of the effect). This is a single study that had a substantial impact on the direction of the field, inasmuch as it set the direction for numerous confirmatory studies that followed. Again, these arguments are valid but they apply in only a small fraction of studies.

Perhaps the key point of Schmidt and Hunter is not that any single objection to the of banning significance tests is or is not valid, but the fact that researchers cling so hard to their beliefs about significance tests. For example, researchers keep coming back to the idea that we need the tests to distinguish between "real" effects and "chance effects," thereby missing the key point: All effects are real. The tests distinguish between studies that showed this and those that (in error) did not. Schmidt and Hunter write "We attribute this psychologically interesting fact to the virtual brainwashing in significance testing that all of us have undergone, beginning with our first undergraduate course in psychological statistics."

Should significance tests be banned, then? Abelson (1997a) wrote that the idea of such a ban is appealing "In the words of a famous empathizer 'I feel your pain'" (p. 118). The abuse of significance tests is so pervasive that it is likely to require some kind of absolute ban to prevent the continued abuse of this tool. If significance tests are allowed to continue, they will continue to be abused, and if the confidence interval is allowed to serve as a surrogate for the significance test, then the door to abuse will be wide open. He notes that abuse would be not only possible, but inevitable: "Indeed, under the Law of Diffusion of Idiocy, every foolish application of significance testing will beget a corresponding foolish practice for confidence limits." Despite these concerns, Abelson concludes that the tests should not be banned. He writes, "Create a list of things that people misuse—for example, oboes, ice skates, band saws, skis, and college educations. Would you be inclined to ban them because people make errors with them? Will we want to ban effect sizes, too, when their misuse escalates?" (p. 13).

While Abelson is correct that the idea of imposing a ban is unappealing, it is also clear that some kind of decisive action is required. Without some concrete and clear action on the part of educators, funding agencies, and journal editors, the shift away from significance tests will drag out over an indeterminate period of time. During this period a great deal of effort will be spent in repeatedly making the case for the shift, harm will be caused, and a great deal of potentially important work will go undone.

It is submit that the appropriate course of action would be not to ban the significance test but rather to require that researchers report effect size indices and confidence intervals. Scientifically, this is more defensible. Pragmatically, this can take effect immediately without further debate. In fact, this requirement is implicit in guidelines now, in the sense that analyses are expected to address the research question and conclusions are expected to follow logically from the analyses. Only rarely do we care about excluding a specific value, and even more rarely do we care about excluding the nil. In virtually all studies, the requirement that analyses address the research question will require that the report highlight the effect size and the precision with which this is reported.

While researchers would be free to report *p*-values in addition to the effect size and confidence interval, it is likely that this practice would disappear because it would become evident that the significance test is of tangential interest, at best. The experience of Rothman is informative in this regard. As an editor at the *American Journal of Public Health*, he took a firm stance against the inappropriate use of significance tests, and in doing so both educated and empowered researchers to focus on effect size in their analyses. More recently, as the editor of *Epidemiology*, Rothman has established a policy that prohibits references to significance testing, but reports that "Interestingly, few readers seem to be aware of this policy, which tells me that they don't miss the absence of claims regarding statistical significance. As you urge, we emphasize the measurement of effect size, and this gets a clear message across to readers."

3.14.7.3 Should the Analysis of the Single Study be Banned?

Similarly, while one can empathize with the desire to ban the analysis of single studies, Schmidt and Hunter overstate their case when they argue that no single study can provide definitive information on its own. Abelson writes, "Indeed, one might say that Hunter and Schmidt use the 'Brooklyn' method of argumentation: The Brooklynite asks you a question, tells you his answer, and then says that you are wrong." The fact is that some studies are well designed, with adequate power and appropriate controls. In fact, some single studies contain more subjects and better designed controls than some meta-analyses. To balance Hunter and Schmidt's point that no substantive issue in psychology has ever been resolved by a single study and that all testing should be deferred to the meta-analysis, we cite a recent editorial in the *New England Journal of Medicine*. Bailar (1997, 1998) noted that no substantive issue in medicine has ever been resolved by a meta-analysis, and that the randomized clinical trial is still considered to be the gold standard. (Bailar acknowledges that meta-analysis hold great potential but objects to the improper use of this procedure. Recall Abelson's prediction, cited earlier.) Additionally, even when the single study cannot yield adequate precision there is a need to provide advice about treatment options based on the evidence at hand, or to use this evidence to help design subsequent research. In such cases the analysis of a single study may be required.

Schmidt and Hunter highlight an important problem when they note that the practice of allowing significance testing for individual studies contributes to the problem of publication bias, but this problem exists, in large part, because researchers and editors focus on the *p*-value. Abelson wrote that in deciding whether or not a study should be published he takes into account five components, including such issues as the role of the study in the context of other research and theory. The *p*-value is a subset of the fifth component, and the least interesting one, at that. If the recommendations outlined above for focusing on effect size are followed, the illogic of basing a publication decision on the significance test should become clear, and the publication bias minimized.

3.14.7.4 Looking Ahead

It seems likely that the shift from significance tests to effect size estimation with confidence intervals is likely to take place over the next several years. Earlier, the history of researchers railing against the null hypothesis tests was outlined, beginning in the 1950s and proceeding to the present. The impact of these writings has been modest. Nevertheless, whether or not significance tests are banned, it is likely that the next few years will be marked by a shift away from significance tests and toward effect size estimation with confidence intervals. This prediction is based on the convergence of several factors (Schmidt, 1996).

The first is a shift in educational resources. Some statistics texts now place more of an emphasis on confidence intervals than they had in the past. Computer programs used for analysis are more likely now than in the past to present confidence intervals as well as tests of significance. Some programs for study planning now incorporate the ability to plan for confidence intervals as well as statistical significance (see, for example, Borenstein et al., 1997 or Elashoff, 1997).

The second is the acceptance of effect size estimation by important segments of the mainstream research community. Journal editors in some fields now encourage or require the use of confidence intervals in research reports (Altman, 1991; Altman et al., 1983; Rothman, 1978, 1986b; Rothman & Yankauer, 1986). The use of confidence intervals is also encouraged in the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* (International Committee of Medical Journal Editors (International Committee of Medical Journal Editors, 1991) [p. 425]). There is now a task force working on behalf of the American Psychological Association, charged with the goal of studying the issues raised in this paper and making recommendations. Harlow et al. (1997) edited a book entitled "*What if there were no significance tests*" and discuss eight points that are endorsed by some or all of the chapter contributors. There is unanimous rejection of the traditional use of significance tests—specifically the exclusive focus on the nil hypothesis and *p*-values. There is unanimous agreement that researchers should present effect size estimates with confidence intervals, should be cognizant of power issues, and should evaluate the results in the context of a theory rather than in isolation. There is strong support, with a few dissenters, for the use of tests that are designed to confirm or refute specific, hypothesis-based theories other than the nil hypothesis.

The third, and most important, factor in this move away from significance tests is the increasingly common application of meta-analyses. Meta-analyses serve both to highlight the flaws in significance tests and to provide a realistic mechanism for the application of effect size estimation. Meta-analysis is the next logical step in the research process and we return to this point at the conclusion of this chapter.

3.14.8 USE OF CONFIDENCE INTERVALS IN STUDIES WHOSE PURPOSE IS TO PROVE THE NULL

Some studies are conducted for the express purpose of showing that the null is true—for example, that two drugs are bioequivalent or that two treatments are equally effective. These studies are framed along the following lines: A study compares the mortality rates in patients treated with either of two drugs. The study has power of 95% to detect a difference of, say, five percentage points in mortality rates and so if the study fails to yield a significant effect we can conclude (with 95% certainty) that the groups do not differ by five percentage points.

The same logic is sometimes applied after the fact to a study which was initially run in hopes of finding a significant group effect. It was shown earlier that the absence of an effect is often interpreted without justification as meaning that the groups are identical. While a conclusion that the treatments are equivalent cannot be justified, one can make the argument that the study had power to detect a difference of some magnitude, and the absence of significance indicates that the groups do not differ by this much. While this approach is technically correct it suffers from two basic flaws.

First, it involves the loss of useful information. Assume, for example, that a study is planned in which schizophrenic patients currently in remission are assigned to treatment with either a low dose or a standard dose of neuroleptic treatment ($N = 40$ per group) and followed for a year. The study has power of 95% to detect a difference of 38 percentage points in recurrence rates (specifically, rates of 0.80 vs. 0.42). Therefore, if the study failed to yield significance it would be fair to conclude that the impact of treatment on recurrence rates, if any, is less than 38 percentage points.

However, the study that fails to yield significance could yield a rate difference of 18 percentage points (0.80 vs. 0.62) with $p = 0.08$ and a 95% confidence interval of -0.02 to 0.35. Or, it could yield a rate difference of two percentage points (0.80 vs. 0.78) with $p = 0.83$ and a confidence interval of -0.15 to 0.18. Once the study is completed it would be inappropriate to fall back on the original computations and report that the rate difference in the population is less than 38 percentage points. Rather, we could report (in the first example) that the rate difference could be as much as 35 points and (in the second) that it is at most 18 percentage points.

Second, the logic of using a power analysis to argue that two groups are comparable is muddled and often misunderstood. We are arguing that if the effect had been of a certain size we would have found it, and we did not, so we can assert that the effect is not that large. Consider, by contrast, the elegant simplicity by which the same information is conveyed in the context of confidence intervals. In the examples cited above we would report that the rate difference falls in the range of -0.02 to 0.35, or the rate difference falls in the range of -0.15 to 0.18. In other words, confidence intervals allow us to report what the effect is rather than what the effect is not (Blackwelder, 1982; Detsky & Sackett, 1985, 1986; Makuch & Johnson, 1986).

The response which had been framed in terms of significance tests and p-values is confusing because the sole function of the significance test is to evaluate the null hypothesis. If we try to reframe the null to mean almost null because we are trying to estimate the magnitude of an effect, then we are using the technique in a manner for which it was not intended and the results are awkward.

3.14.9 COMPUTATIONAL ISSUES IN CONFIDENCE INTERVALS

Earlier, it was noted that a confidence interval could be approximated as the observed effect plus/minus a specified distance. This is a shortcut that yields approximate results, and two caveats are in order. First, even for this approximation the computation is somewhat more complex than suggested here. If the index is based on a mean difference, then to compute the 95% interval we would multiply not by 1.96 but by a factor, based on the t-distribution, that takes sample size into account. Additionally, for most indices, including those based on proportions or correlations, we would transform the data prior to computing the confidence interval and then convert back to the original metric prior to reporting the results. Formulas for these transformations are widely available (Fleiss, 1981; Kleinbaum et al., 1982; Rothman, 1986a; Selvin, 1991) and are applied as a matter of course by computer programs. Second, even when these transformation are applied, for most indices the result is still approximate. While the approximation yields an interval that is accurate enough for most purposes, it is not identical to the interval obtained by more sophisticated procedures (see, for example, Cornfield, 1956; Fleiss, 1979, 1981). The assertion that the 95% confidence interval will exclude the null if and only if the significance test is significant at 0.05 assumes that exact formulas (or the identical approximation) are used for computing the p-value and the confidence interval.

3.14.10 STUDY PLANNING: PRECISION ANALYSIS VS. POWER ANALYSIS

If the goal of a study is to yield a test of significance, it follows that the study should have adequate power to yield a significant effect. By the same logic, if the goal of a study is to provide an estimate of effect size, it follows that the study should be able to provide this estimate with an acceptable degree of precision. While the research community is clearly moving toward effect size estimation for data analysis, relatively little has been said about the need for a corresponding shift in the mechanisms used for study planning. In fact, it is not unusual to see a paper that focuses on effect size in the analysis but whose sample size was set on the basis of a power analysis. There is neither a mathematical nor a logical basis for this mixture of apples and estimates. The two goals, significance tests and effect size estimation, have in common that they are both things we can do with data. Beyond this, however, the two criteria are quite different.

Power addresses the likelihood that a study will yield a significant effect. As such, it is controlled by effect size, sample size, and alpha—the same elements that control statistical significance. Precision addresses the width of the confidence interval surrounding the effect size estimate. As such, it is controlled by the confidence level and the sample size—the same elements that control the confidence interval width. Of particular note, effect size is the dominant factor in computation of power but plays little (if any) role in the computation of precision. The sample size required to yield adequate power and the sample size required to yield adequate precision will differ from each other in almost all cases, and often by very substantial amounts.

3.14.10.1 Planning for Precision

To determine the study's precision during the process of study planning, we may "plug in" the sample size and confidence level, and compute the confidence interval width that will result. As was the case for power analysis, this process is facilitated by computer programs designed for this purpose.

Figure 8 is an example of this process using the program cited earlier for power analysis. On this panel the researcher has entered response rates of 60% and 40% for the new treatment and the standard treatment, respectively, and a sample size of 190 patients per group. The program displays the effect size as a rate difference of 20 points. This effect will be reported with a 95% confidence interval of plus/minus 10 points (0.10–0.30).

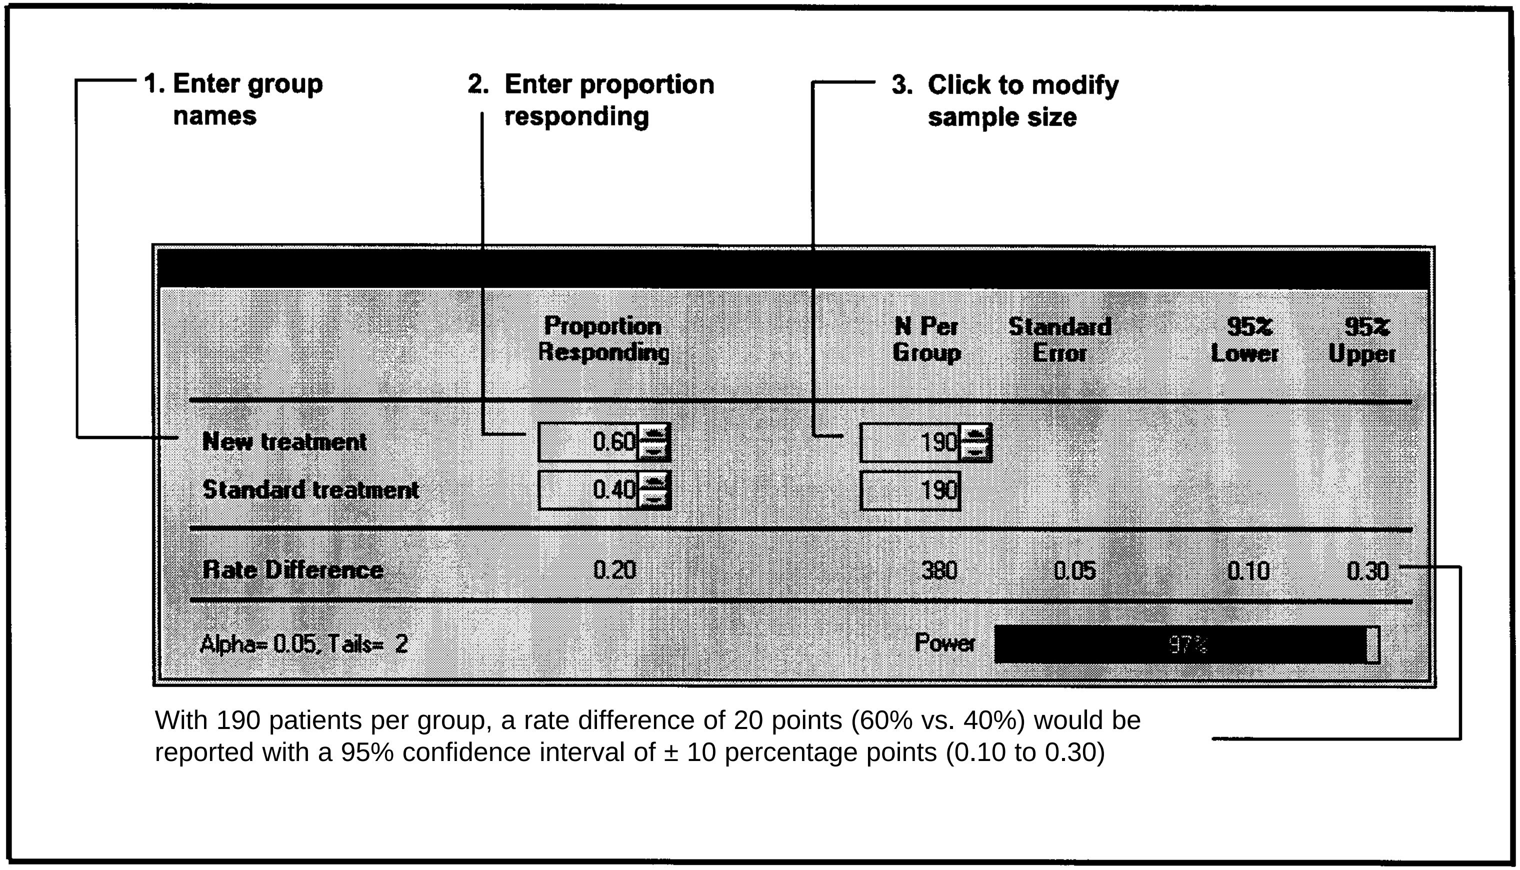
The researcher may modify the sample size—increases to sample size will yield a more precise estimate. The researcher may modify the confidence level—setting the level at 90% rather than 95% will yield a narrower interval. If the study index is a mean difference, the researcher may modify the standard deviation (SD) within groups—a smaller SD will yield a narrower interval. The researcher may also modify the effect size but, as noted earlier, the confidence interval width will be affected only slightly, if at all.

It should be noted that Figure 8 is an extension of the example cited earlier for power (Figure 3). In that case the researcher had determined that a sample of 107 patients per group would yield power of 80%, and the confidence interval is shown as 0.07–0.33. When planning for precision the researcher has increased the sample size to 190 to yield a more precise estimate of the effect size, and power has increased as well, from 80% to 97%.

As it did for power, the program will generate a table or graph of precision that allows us to quickly take account of the larger picture (Figure 9). With 50 patients per group we will be able to report the rate difference with a precision (95% confidence interval) ± 20 percentage points. With 100 patients per group we will report the rate difference with a precision of ±13 percentage points. With 200 patients per group we will report the rate difference with a precision of ±10 percentage points.

The program will also generate a summary of the analysis. This report reads (in part) "A second goal of this study is to estimate the difference between the two populations ... The study will enable us to report the difference in proportions with a precision (95.0% confidence level) of approximately ± 0.098 points. Specifically, an observed difference of 0.200 would be reported with a 95.0% confidence interval of 0.100–0.296. The precision estimated here is the approximate expected precision. Precision will vary as a function of the observed proportions (as well as sample size), and in any single study will be narrower or wider than this estimate."

In this example the power analysis led to a sample size requirement of 107 per group while the precision analysis led to a sample size of 190 per group. In other studies the relationship between the two sample sizes will be different, and could even be reversed (with the sample for power being larger than the sample for precision). The key point is that the two goals of significance testing and effect size estimation are distinct. Precision analysis focuses on the precision of the estimate rather than the power to test the null hypothesis, and as such is the appropriate method to use when the study goal is to estimate the magnitude of the treatment effect (Bristol, 1989; Burnand et al., 1990; Cobb, 1985; Feinstein, 1990; Gordon, 1987;



1. Enter group names

2. Enter proportion responding

3. Click to modify sample size

	Proportion Responding	N Per Group	Standard Error	95% Lower	95% Upper
New treatment	0.60	190			
Standard treatment	0.40	190			
Rate Difference	0.20	380	0.05	0.10	0.30

Alpha= 0.05, Tails= 2

Power 97%

With 190 patients per group, a rate difference of 20 points (60% vs. 40%) would be reported with a 95% confidence interval of ± 10 percentage points (0.10 to 0.30)

Figure 8 Screen from power and precision showing computation of precision. The effect size is shown as a rate difference of 20 points with a 95% confidence interval of 0.10–0.30. The researcher may modify any of the study parameters such as sample size and confidence level and immediately see the impact on the confidence interval width.

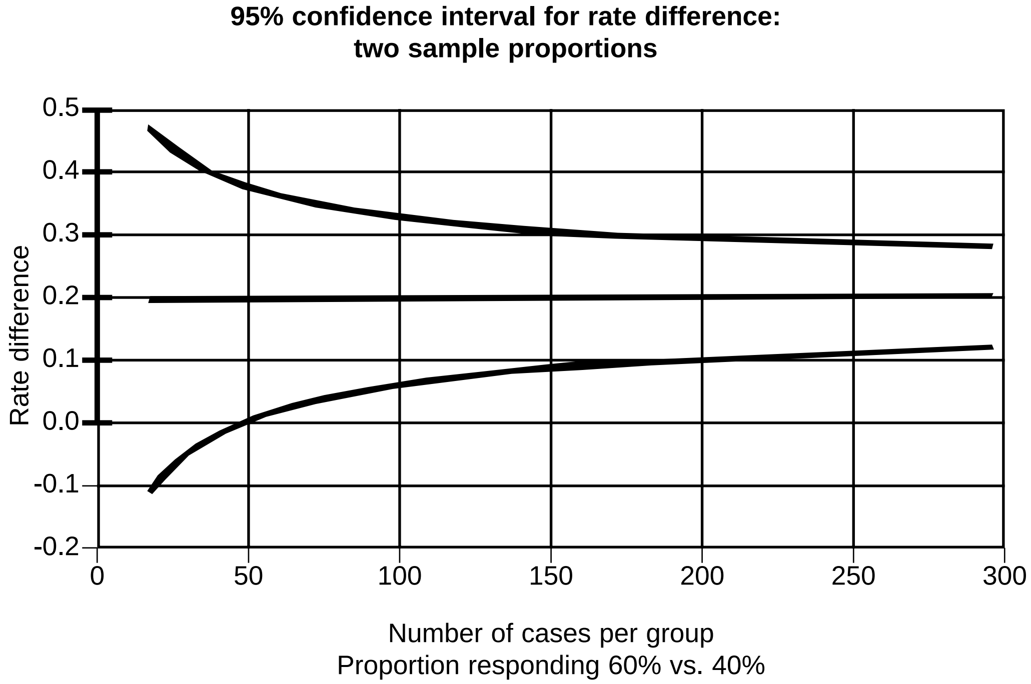


Figure 9 Planning for precision. With a sample of 50 cases per group the treatment effect will be reported with a 95% confidence interval some 40 percentage points wide. With 100 cases per group the interval will narrow to 30 points, and with 200 per group the interval will narrow to 20 points.

Greenland, 1988; Oakes, 1986; Smith & Bates, 1992; Walter, 1991).

Of course, even a fairly narrow interval may include some effects that are clinically meaningful and others that are not, but as the interval narrows in width it becomes increasingly likely that the study results will provide the information required for an informed clinical decision. In many cases, the sample size required for a precise estimate will exceed the available resources. For example, if only 50 cases per group are available, then the 95% interval will be nearly 40 points wide. In this case the study could still provide data that would be pooled with data from other studies, in a meta-analysis.

The method presented here for planning for precision shows provides an estimate of the confidence interval width, but the actual confidence interval in any given study will almost always be narrower or wider than the width estimated in this way. When working with means, for example, the confidence intervals are based in part on the sample standard deviation, which will vary from one sample to the next. When working with proportions, correlations, or survival data the confidence intervals are based in part on the absolute effect size obtained which will vary from one sample to the next. The procedure outlined here is based on the assumption that the sample effect will mirror the population effect precisely. As such, it yields the median confidence interval width for some procedures and the expected (mean) width for others. Computer programs use more complex formulas that take account of the sampling distribution of the confidence intervals. As such they may allow us to report, for example, that "With a sample of 50 cases per group and a standard deviation of 10 rating points within groups, the median width of the confidence interval will be 7.9 points. In 80% of studies, the confidence interval will be no wider than 8.4 points." If the researcher needs to ensure that the confidence interval width will fall within a specific range, then these formulas should be employed (Borenstein et al., 1997; Elashoff, 1997; Hahn & Meeker, 1991).

3.14.11 META-ANALYSIS

Meta-analysis is the process of developing a comprehensive picture of a field of research by performing analyses on summary data from individual studies, and as such is the next logical step in the research process. The thesis of this chapter has been that the goal of research should be to identify the size of a treatment effect. The single study, because it includes a limited number of subjects, typically yields an imprecise estimate. By combining data from multiple studies we effectively increase the sample size and yield a more precise estimate of the effect. Additionally, the single study typically includes one treatment and one treatment population. The meta-analysis, by contrast, may synthesize data from multiple treatments or multiple populations, and as such may be used to identify the type of treatment that will work best for a specific type of patient. Meta-analyses are being used to provide treatment recommendations based on the results of completed studies. They are also being used to identify areas where the questions of interest have not yet been answered, and to help shape the development of new studies.

The relatively widespread acceptance of meta-analysis since the late 1980s has important implications for the topic of this chapter in a more direct sense as well. The thesis of this chapter is that in psychological research the null hypothesis is rarely true, and what appear to be "conflicting results" (one study is statistically significant while another is not) often reflects normal sample-to-sample variation in effect size coupled with variations in sample size. In past decades this argument had been made in the abstract. With the advent of meta-analysis it is possible to actually "see" the bigger picture. Almost invariably, it becomes clear that the null hypothesis is false, and the study-to-study variations can be seen in context. This has been a critical factor in the shift toward effect size estimation (Cook et al., 1992; Cooper, 1989; Cooper & Hedges, 1994; Eagly & Wood, 1994; Hedges, 1990; Hedges & Olkin, 1985; Schmidt & Hunter 1997; Shadish, 1992).

3.14.12 CONCLUSIONS

Researchers typically want to know whether or not a treatment has any impact, and also what the size of this impact might be. Researchers working exclusively with significance tests are able to address only the first of these issues, and leave the second unanswered. Worse, because the issue of effect magnitude is such a compelling one, the significance tests are often pressed into service to address this issue as well, which often leads to study results—whether statistically significant or not—being misinterpreted. Statistical significance is equated with clinical significance, though this interpretation may not be warranted. Absence of statistical significance is taken as evidence that a treatment is not effective, though this interpretation is rarely justified.

By contrast, estimates of effect size bounded by confidence intervals provide the kind of information that researchers and clinicians require. The report of effect size focuses attention on the magnitude of the effect, and the confidence intervals tell us how much confidence we can have that the population effect lies within a given range. The data may allow us to conclude that the treatment is clearly not effective, or that it clearly is effective, or that additional information is required. Critically, though, this type of report focuses attention on the relevant issues. If and when we elect to make a dichotomous decision, the format of the presentation helps to ensure that the meaning of this decision is clearly understood.

There is an ongoing debate about the role of the single study as part of the research process. Some take the position that any single study should allow researchers to conclude that a specific effect size is or is not tenable. Others have argued that the single study cannot provide this kind of information reliably, and that hypothesis testing should be deferred to the time that the data from many studies can be synthesized in a meta-analysis.

This debate has carried over to the role of confidence intervals. There is complete agreement that researchers should present the effect size bounded by confidence intervals since this will focus attention of the issue of interest and will help to prevent mistakes of interpretation. However, there is sharp disagreement over how the confidence interval should be interpreted. Some take the position that confidence intervals should serve as a surrogate for the significance test, and the focus should be in the question of whether or not the interval includes a specific value. When used in this way the shift from significance tests to confidence intervals is one of format rather than substance—it helps to focus attention on the proper issue and to avoid mistakes of interpretation. Others feel that this approach will merely codify the kinds of errors inherent in significance tests. They argue that the key element in a shift to confidence intervals should be the abandonment of significance testing, and that one should refrain from any discussion of whether or not specific points fall within the interval.

The issues addressed in study planning should correspond to the issues that will be addressed in the data analyses. If the goal of a study is to yield a test of significance, the study should have adequate power to yield a significant effect. Similarly, if the goal of a study is to provide an estimate of effect size that can stand on its own, the study should be able to provide this estimate with an acceptable degree of precision. Prior to ensuring that the power analysis is performed properly it behooves the researcher to ensure that it makes sense to test the null, and indeed that the study should be carried out at all.

The argument that effect size estimation and confidence intervals should replace significance testing in behavioral research is not new but the research community is beginning to take concrete steps in this direction. This shift has been driven by the advent of meta-analysis. Meta-analyses have served to highlight the kinds of errors that are fostered by the use of significance tests, and at the same time provide a vehicle for estimating treatment effects precisely. Additionally, they provide a vehicle for moving beyond the single study and for synthesizing data from multiple sources, which is the next logical step in the research process.

3.15.1 INTRODUCTION

3.15.1.1 A Brief History

A little over 20 years ago, educational researcher, Gene V. Glass was interested in the question of the whether psychotherapy works. In other words, does it help patients any more than would a placebo treatment? Furthermore, if in fact psychotherapy overall is effective, can it be determined whether one form is more effective than another? Glass was not the first researcher interested in this question. Hundreds of studies had previously been conducted in this area. Yet the results from these studies, and even from reviews which summarized the studies, had reached contradictory conclusions. What was unique about Glass' attempt to answer this question was that he was the first to conduct a quantitative synthesis of the research, a procedure which he called a "meta-analysis" (Glass, 1976; Smith, Glass, & Miller, 1980). In conducting the meta-analysis, Glass first located studies which asked this question of whether psychotherapy works and then he quantitatively characterized the outcomes and features of the studies and statistically described his findings. Glass ultimately found that psychotherapy shows positive results and that there is little difference between the different types of therapy.

While Glass is responsible for coining the term and for carrying out the first large-scale meta-analysis, meta-analytic enterprises had previously been undertaken. For example, in 1904, Karl Pearson, the inventor of the Pearson product moment correlation coefficient, had been investigating the degree to which inoculation against smallpox saved lives. He collected the following six correlation coefficients (r's) which measured the relationship of inoculation to survival: 0.58, 0.58, 0.60, 0.63, 0.66, and 0.77, and averaged them, finding a mean correlation of 0.6. Thus, his "meta-analysis" or synthesis of these six studies found a rather large effect of inoculation on survival.

In the 1930s, Ronald Fisher was experimenting with combining significance levels of independent studies (Fisher, 1938) as were Frederick Mosteller and Robert Bush in the 1950s (Mosteller & Bush, 1954). Mosteller and Bush also showed the usefulness of combining effect sizes as well as significance levels. Even in George Snedecor's 1946 statistics textbook is included an example drawn from agriculture of combining correlation coefficients measuring the relationship between the initial weight of steers and their subsequent gain in weight. Finally, back to the field of psychology, in early work on experimenter expectancy effects in the 1960s, there is an example of combining three probability levels to give an overall test of significance of three experiments (Rosenthal, 1966).

Since Glass' use of the term, meta-analyses have become widely used for research in the behavioral and physical sciences and in applied situations, such as for policy making. By one estimate, nearly 2000 meta-analytic reviews have been conducted in the social and health sciences between 1980 and 1994 (Bausell, Li, Gau, & Soeken, 1995). In addition to the growing numbers of meta-analyses that have been conducted, a number of different procedures for conducting meta-analyses have also been described. Indeed, whole books, not to mention numerous individual papers and chapters, have addressed the issue of conducting meta-analyses (e.g., Cooper, 1989; Cooper & Hedges, 1994; Glass, McGaw, & Smith, 1981; Hedges & Olkin, 1985; Hunter & Schmidt, 1990; Light & Pillemer, 1984; Rosenthal, 1991). This chapter will illustrate the basic quantitative procedures for conducting a meta-analysis. This chapter draws on material presented in Rosenthal, (1984, 1991, 1993, 1995a, 1995b, 1998) and in Rosenthal and Rosnow (1991). For more detailed information about the procedures discussed here, the reader may wish to consult these sources. As the chapter will demonstrate, the level of quantitative skill and training required to employ basic meta-analytic procedures is so modest that any researchers capable of analyzing the results of their own research will be capable of learning the small number of calculations required to conduct a first-rate meta-analysis.

3.15.2 WHY DO A META-ANALYSIS?

3.15.2.1 The Problem of Poor Cumulation

A meta-analysis is literally an analysis of analyses or a procedure for quantitatively cumulating research results addressing specific research questions. Unlike a typical literature review, a meta-analysis addresses the problem of "poor cumulation" in the social sciences. It is quite common to find a literature review in which dozens of studies are discussed but which ends with a call for more research. When these studies are discussed within the review, only the statistical significance or nonsignificance of the results, without any information about the size of the effects, are presented. Until somewhat recently, when there existed only a small number of studies in any given research area, it was easier to form conclusions about a body of research, but now, as hundreds of studies have been conducted in many fields in the social sciences, the problem of poor cumulation continues to grow.

Unlike the physical sciences in which newer work builds directly upon the older work, in the social sciences each succeeding volume of our scientific journals almost seems to be starting anew, posing the same research questions time and again. The common explanation for this problem is that there is more variability or less agreement in our field which prevents the kind of building seen in other fields. Yet, this commonly held belief has not been supported. A recent comparison of 13 research areas in particle physics with 13 areas in psychology did not actually find more conflicting results in our field (Hedges, 1987). For the researcher trying to develop theory, for the practitioner trying to decide on treatment, for the policy maker trying to change policy, and for the funding agency trying to allocate research money, meta-analysis holds great promise.

3.15.2.2 Primary Purposes of Meta-analyses

The first primary purpose of a meta-analysis is to summarize for a set of studies the overall relationship between the two variables that had been investigated in each study. It can be used, as with the Glass psychotherapy meta-analysis, for pulling together hundreds of studies, or it can also be used simply by an investigator asking whether a study and its replication produce similar or different results and what the net results of these two studies might be. By quantitatively summarizing the existing research, a meta-analysis is able to discover what has so far been learned and help to discover what has not yet been learned.

Another equally important purpose of meta-analytic work is to learn from comparisons between studies. By comparing the studies in a meta-analysis, the researcher hopes to determine factors that are associated with variations in the magnitudes of the relationships between two variables. These factors are known as moderator variables because they moderate or alter the magnitude of a relationship. For example, a meta-analysis might suggest that the effectiveness of a given type of therapy is moderated by the age of the patient, such that it is more effective with adolescents but less so with adults. By comparing studies, the meta-analysis uncovers new relationships or provides support for suspected relationships, thus paving the way for future research.

3.15.2.3 Pooling Pilots

While meta-analysis is potentially valuable in all fields, it can be particularly helpful for clinical research. Often in clinical research, the number of patients available is so small that all the researcher is able to do is to conduct pilot studies, none of which will ever reach a significance level of $p < 0.05$. However, the researcher is able to combine these individual studies meta-analytically. A recent example of this appeared in an issue of *Science* (Cohen, 1993) which described two pilot studies in which experimental monkeys were vaccinated using SIV (akin to HIV), while control monkeys were not. In the first pilot, six monkeys were available, three vaccinated and three controls. The results showed two of the three vaccinated monkeys and none of the three controls in better health ($p = 0.20$, one-tailed). In the second pilot, 11 animals were available and two of five of the experimentals and none of six of the controls wound up in better health ($p = 0.18$, one-tailed). While the results of neither one of these tiny pilot studies was significant, if treated meta-analytically, they show dramatic benefits of vaccination.

3.15.3 CONDUCTING A META-ANALYSIS

3.15.3.1 Formulating the Question

The first step in conducting a meta-analysis, as with any research enterprise, is a clear formulation of the question being examined. The only constraint on the question is that primary research on the topic must have already been conducted. The specificity and clarity of the question is especially important in a meta-analysis in that it will help the researcher define the criteria for inclusion (see below). The primary question the meta-analysis seeks to answer is: what is the relationship between any variable X and any variable Y? In order to answer this question, we need to have

(i) an estimate of the level of significance of the difference between the obtained effect size and the effect size expected under the null hypothesis (usually an effect size of 0). Estimates of levels of significance are expressed by p values associated with the given significance test, such as t, F, chi-square or Z;

(ii) an estimate of the magnitude of the relationship between X and Y (an effect size). An effect size commonly used by Glass and his colleagues is the number of standard deviation units that separate outcome scores of experimental and control group, expressed as d.

According to Cohen (1977), d's around 0.2 are considered small, around 0.5 are considered medium, and around 0.8 are large. A concrete example of the meaning of an effect size which is drawn from educational research is that a d of 0.2 would raise a student's performance from the 50th percentile to the 58th percentile, a 0.5 would raise it to the 69th, and a 0.8 would raise it to the 79th percentile (Cohen, 1977). Another common effect size estimate is given by r. The relationship between r and d is $r = d \,/\, [(d^2 + 4)^{12}]$.

The relationship between an effect size and a significance test is given by:

$$\text{test of significance} = \text{size of effect} \times \text{size of study} \qquad (1)$$

Table 1 provides several examples of this relationship.

As this basic equation illustrates, as a study increases its sample size, it will obtain more significant results (except in the unusual case where an effect size is truly zero in which case a larger study will not produce a result any more significant than a smaller study). An effect size, however, would not be affected by the size of the sample used in the study.

3.15.3.2 Defining Criteria for Inclusion

Once the research question has been formulated, the next step in the meta-analysis is a careful consideration of what criteria must be met in order for a study to be included in the synthesis. For example, a study comparing individual to group therapy would need to define what constitutes group therapy. Would couples therapy meet these criteria; would therapy which combines group meetings with individual sessions meet these criteria? Deciding on the criteria should be theory or hypothesis driven. For example, if previous research had found that couples therapy is fundamentally different from group therapy, then studies with couples should be excluded from the meta-analysis.

Regardless of the specific question being examined, a basic criterion for inclusion in the meta-analysis is that the studies have reported, or have provided the necessary information for us to obtain, an estimate of an effect size and a significance level for each study. Studies which do not provide this information or a way for the reader to derive this information are not ordinarily included in the analysis.

3.15.3.3 Searching the Literature

There are four basic types of documents from which studies may be retrieved: (i) published books or book chapters; (ii) published journal articles, magazines, newsletters, and newspapers; (iii) bachelor's, master's, and doctoral theses; (iv) unpublished works such as technical reports, convention papers, or raw data. There are a number of computer databases available to help with the retrieval process, such as PsycLit or PsycInfo (see Dickersin, 1994; Reed & Baxter, 1994; Rosenthal, 1994; White, 1994 for specific details on helpful retrieval techniques). Because successful retrieval from these databases is dependent on identifying the right keyword or key subject, the searcher may occasionally miss some references. Therefore, retrieval should also rely on the "ancestry approach," also known as "footnote chasing" (White, 1994), which involves searching reference lists of relevant articles and books. Past issues of relevant

Table 1 Examples of the relationship between tests of significance and effect size: chi-square, Z, t, and F.

Test of significance	=	*Size of effect*	*x*	*Size of study*
$\chi^2_{(1)}$	=	ϕ^2	x	N
Z	=	ϕ	x	$\sqrt{N}$
t	=	$\frac{r}{\sqrt{1-r^2}}$	x	$\sqrt{df}$
t	=	d	x	$\frac{\sqrt{df}}{2}$
F	=	$\frac{r^2}{\sqrt{1-r^2}}$	x	df
t^{a}	=	d	x	$\sqrt{df}$

[a] Correlated observtions.

journals should also be hand searched. Finally, if primary researchers in the field can be contacted, they should be consulted for their knowledge of any unpublished work in the field by themselves or by their colleagues. This last method has been referred to as using the "invisible college" grapevine (Crane, 1972).

A comprehensive search for all the research on the given topic is necessary in order to avoid conducting a biased retrieval of only the major journals which may selectively publish results characterized by lower *p* values. If the field we are searching is too vast for us to analyze every study, it is better to sample randomly from this complete selection than to analyze only the more readily retrievable results.

3.15.3.4 Recording Study Characteristics and Identifying Moderators

In addition to an estimate of effect size and a level of significance, there are always other features of the retrieved studies that will be of interest both for purely descriptive purposes and for analysis as potential moderating variables. For example, the meta-analyst should always record and report the following study characteristics: (i) descriptions of the participant population, such as number, age, sex, education, and volunteer status; (ii) descriptions of how the study was conducted, such as whether it was conducted in a laboratory or in the field, whether it was observational or randomized; and (iii) year and form of publication of the study. In addition to listing each study and its relevant characteristics, it is also good meta-analytic practice to provide the range and median of these features, such as the range and median of dates of the studies and ages of the participants.

All of the study characteristics recorded can also be employed as moderator variables, that is, variables correlated with the magnitude of the effect size obtained for the different studies. For example, a meta-analysis conducted by social psychologist Alice Eagly on sex differences in influenceability found that the time when a study was published was strongly related to the study's results. Studies published before 1970 were somewhat more likely to show greater influenceability among females, while studies published during the period of the women's movement in the 1970s were less likely to find differences between sexes (Eagly & Carli, 1981).

In addition to these general characteristics, each area of research will also have its own specific moderator variables which are of particular interest or meaning. For example, a meta-analysis in the field of the effects of teachers' expectations on pupils' IQ gains specifically looked at the possible moderator variable of how long teachers had known their pupils before the expectations were assigned (Raudenbush, 1994). This analysis found that the longer teachers had known their pupils before the experiment began, the smaller were the effects of experimentally-induced teacher expectations. One method of organizing the various relevant variables that has often proven helpful is to break down the variables into substantive and methodological variables. Substantive variables are those relating to the phenomenon under investigation while methodological variables are those that relate to the procedural aspect of the study (Lipsey, 1994). Some examples of substantive features might be type of treatment administered or characteristics of the subject population. Some methodological variables of interest might be variations in the research design or procedure or internal validity of the study (e.g., random assignment of participants to conditions or use of a control group).

An example of a methodological variable from the study of female influenceability mentioned above that was found to play a large role was the sex of the researcher (Eagly & Carli, 1981). In this meta-analysis, male researchers were more likely to find female influenceability in their studies than female researchers. An explanation for this finding may be that if a difference was found between the sexes, it was equally as likely to be reported by male and female researchers. However, if no difference was found, a male researcher would tend to report the results less often than a female researcher who would be more likely to see the absence of an effect as important in that it disputes the stereotype of females being more conforming and persuasible. After forming a preliminary list of moderators which have been identified, this form should be discussed with colleagues, advisors, and other workers in the field for suggestions of other moderators that should be coded.

3.15.3.5 Coding

Once relevant features have been identified, they need to be coded and entered into a database type of system. Some variables, such as subject sex or number of subjects in the study, can be easily coded (e.g., a 1 for female subjects or a 0 for males). Others, such as an assessment of the quality of the study, will require more sophisticated coding. For these types of codings, each study should be coded by several knowledgeable methodologists who are not necessarily specialists in the field being examined. The agreement or reliability of the judges can then be assessed (for details on how to compute reliability, see Rosenthal, 1991 or Rosenthal & Rosnow, 1991) and when agreement is satisfactory the feature is coded. Table 2 provides an example of a partial database of relevant variables which were coded from a recent meta-analysis examining individual vs. group problem-solving performance (Kramer & Rosenthal, 1997).

3.15.3.6 Descriptive Data Displays

Once all the studies have been collected and the relevant information extracted and recorded from each, the next step is to display what has been found. One of the most important parts of a meta-analysis is a graphic display of the effect sizes and the summary of their distribution and central tendency. We will describe two visual displays that may be used, but there are a great many more to choose from (e.g., Cooper, 1989; Glass et al., 1981; Greenhouse & Iyengar, 1994; Hedges & Olkin, 1985; Light & Pillemer, 1984; Light, Singer, & Willett, 1994; Rosenthal & Rosnow, 1991; Tukey, 1977).

3.15.3.6.1 Stem and leaf

Table 3 is a stem and leaf display (Tukey, 1977) from a recent meta-analysis of the effects of gender on judgments of sexual harassment (Blumenthal, 1997). Each of the 83 effect sizes is recorded with the first digit found in the column labeled "stem" and the second digit found in the column labeled "leaf." The top two entries of Table 3, therefore, are read as two *r*'s of 0.65, and 0.43. The stem and leaf display provides a clear overall impression of all of the results; in this particular case, the display quickly and easily demonstrates that most of the effects of gender differences found in these studies tend to be small. It can also point out when there is an unusual distribution of effect sizes, for example, a bimodal distribution may suggest that a certain innovation works well for one group but not for another.

3.15.3.6.2 Box plot and summary table

The box plot or box graph, originally called a box-and-whisker plot (Tukey, 1977), provides a pictorial summary of five descriptive statistics from the distribution of effect sizes: the maximum, the minimum, the median, the 75th percentile, and the 25th percentile. Figure 1 displays a box plot of the data in Table 3. The top and bottom dots represent the maximum and minimum scores, the top and bottom of the rectangle represent the 75th and 25th percentile and the line dividing the rectangle represents the median. The box plot is especially useful when there are data to display from several subsamples.

In addition to the graphic display, it is also instructive to provide a summary table of these measures of central tendency and variability. Several indices of central tendency should be reported: the unweighted mean effect size, the weighted mean effect size, (see below for more details on weighting), and the median. The number of independent effect sizes on which these indices are based should be reported. The standard deviation, the maximum and minimum effect size, and the effect sizes found at the 75th percentile (Q3) and the 25th percentile (Q1) should also be given. The following may also be reported: the proportion of studies showing effect sizes in the predicted direction; the total number of subjects on which the weighted mean is based; and the median number of subjects per obtained effect size. Table 4 provides a summary of the data displayed in the box plot in Figure 1.

3.15.4 QUANTITATIVELY ANALYZING THE STUDIES

In addition to the descriptive techniques just discussed, there are also procedures for inferential analysis of the retrieved data. As Table 5 shows, there are two major ways to evaluate the results of research studies: (i) terms of their statistical significance (e.g., *p* levels); and (ii) in terms of their effect sizes (e.g., *r*). When evaluating, there are two major analytic processes that can be applied to the set of studies: comparing and combining. Because there are some especially convenient computational procedures for the two-study situation, Table 5 separates the procedures applicable to the case of combining and comparing two studies from three or more studies. In cases of three or more studies being represented, we are able to compare studies on two levels: with diffuse tests and with focused tests. When diffuse tests are used to show whether significance levels or effect sizes differ, the researcher may learn that they differ but not how they differ. By using focused tests, or contrasts, we are able to expand on the knowledge of the diffuse tests by learning whether the studies differ in a theoretically predictable or meaningful way.

3.15.4.1 Comparing Two Studies

3.15.4.1.1 Significance testing

Although we are generally more interested in comparing the results of the effect sizes of the

0.0	0,0,0,0,0,0,0,0,0,3

two studies, sometimes this information is not available and all we are able to compare is p values. The following is the procedure for comparing the significance levels of two studies (Rosenthal & Rubin, 1979); all p levels are one-tailed. First, for each of the studies, we obtain as exact a p level as possible. For example, if we obtain $t(150) = 2.32$, our $p = 0.011$ not <0.05. Extended tables of the t distribution are helpful here (e.g., Federighi, 1959; Rosenthal & Rosnow, 1991) or calculators and software packages with built-in distributions of Z, t, F, and chi-square that will provide exact p values for the various statistical tests. Second, for each p, we find Z, the standard normal deviate corresponding to the p value (using a Z table or calculator or statistical software that converts from p to Z). Since only one-tailed p's were used, if both Z results are in the same direction, they will both have positive signs; if the results are in the opposite direction, one of the two Z's will be negatively signed. The two Z's are then compared by the following formula:

$$Z = \frac{Z_1 - Z_2}{\sqrt{2}} \qquad (2)$$

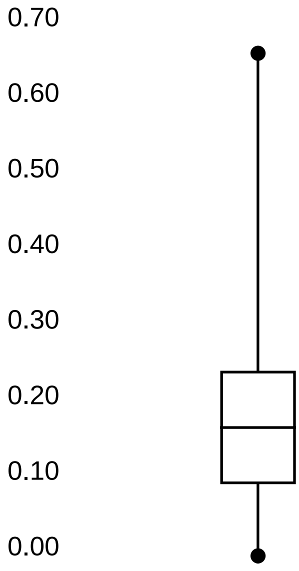

Figure 1 A box plot of the data displayed in Table 3.

Example 1

Studies A and B yield results in the same direction; one is significant at the 0.05 level, the other is not. The p level of Study A is 0.04, the p level of Study B is 0.30. The Z's corresponding to these p's are found in a table of the normal curve to be 1.75 and 0.52 respectively. Using Equation (2), we find that:

$$\frac{Z_1 - Z_2}{\sqrt{2}} = \frac{1.75 - 0.52}{\sqrt{2}} = 0.87$$

The p value associated with this Z is 0.19 one-tailed. Thus, when comparing these two studies, one of which reaches "significance," while the other does not, we find that the difference between them does not come close to the conventional levels of significance. The examples in the chapter are hypothetical in order to keep the computational examples small and manageable. For illustrations of various meta-analytic procedures with real-life examples, see the final chapter in Rosenthal (1991).

Example 2

Studies A and B yield results in different directions and both are significant. One p is 0.001, the other is 0.03. The Z's corresponding to these p's are 3.09 and -1.88 (note the opposite signs to indicate results in opposite directions). From Equation (2), we have:

$$\frac{(3.09) - (-1.88)}{\sqrt{2}} = 3.51$$

which has a corresponding p of 0.0002, which indicates that the two p values differ significantly.

3.15.4.1.2 Effect size estimation

When comparing studies, we are usually more interested in looking at the consistency or heterogeneity of the effect sizes than of the significance levels since a difference in Z's might simply be due to the difference in the size of the studies but not truly reflective of whether the two studies differ in effect size.

Researchers do not routinely report an effect size estimate together with their test of significance. Yet, in most cases, by rearranging the formulas in Table 1 into the following formulas, the meta-analyst can compute the

Table 4 A summary table of the measures of central tendency and variability of the distribution of effect sizes in Table 3.

Central tendency		*Variability*	
Unweighted mean	0.17	Maximum	0.65
Weighted mean	n.a.	Q3	0.23
Median	0.15	Median	0.15
Proportion of studies greater than 0.00	0.89	Q1	0.09
		Minimum	0.00
Median number of subjects per effect size	n.a.	Q3–Q1	0.14
		Standard deviation	0.13
Total number of independent effect sizes	83		
Total number of subjects	34 350		

n.a. = information not available

necessary effect size from the information that has been reported. There are several ways of computing effect sizes (*r*) from significance test results (*t*, *Z*, chi-square, and *F*) as shown below.

$$r = \sqrt{\frac{t^2}{t^2 + df}}$$

$$r = \sqrt{\frac{x^2(1)}{N}}$$

$$r = \frac{Z}{N}$$

$$r = \sqrt{\frac{F(1,\_)}{F(1,\_) + df_{error}}}$$

The effect size emphasized in this chapter will be *r* but analogous procedures are available for comparing other effect size indicators such as Hedge's *g* or *d′* (Hedges, 1982; Hsu, 1980; Rosenthal, 1991; Rosenthal & Rubin, 1982a; Rosenthal, Rosnow, & Rubin, 1997).

As the population value of *r* gets further and further from zero, the distribution of *r*'s sampled from that population becomes more and more skewed. To adjust for this skew, it is recommended that all *r*'s first be transformed to Fisher z_rs (Fisher, 1928), which are distributed nearly normally, before further computations are carried out. The relationship between *r* and *z* is given by $1/2 \log_e [(1 + r)/(1 - r)]$. There are handy tables available which convert *r* to z_r and z_r to *r* (e.g., Rosenthal & Rosnow, 1991) and most statistical software packages will easily perform this transformation as well. After converting obtained *r*'s to z_r's, the following formula may be used:

$$\frac{z_{r_1} - z_{r_2}}{\sqrt{\frac{1}{n_1-3} + \frac{1}{n_2-3}}} \qquad (3)$$

which is distributed as *Z* (Snedecor & Cochran, 1989).

Example 3

Studies A and B yield results in the same direction with effect sizes of $r = 0.70$ ($n = 25$) and $r = 0.25$ ($n = 100$), respectively. The Fisher z_r's corresponding to these *r*'s are 0.87 and 0.26, respectively. From Equation (3), we have

$$Z = \frac{z_{r_1} - z_{r_2}}{\sqrt{\frac{1}{n_1-3} + \frac{1}{n_2-3}}} = \frac{0.87 - 0.26}{\sqrt{\frac{1}{22} + \frac{1}{97}}} = 2.58$$

which has an associated p of 0.005, one-tailed. Thus, these two studies agree on a significant positive relationship between variables X and Y but disagree significantly in their estimates of the size of that relationship.

3.15.4.2 Combining Two Studies

3.15.4.2.1 Significance testing

While comparisons of two studies allow us to ask whether our studies differ in some way, it is also of interest to combine the two studies. By combining the significance levels of two studies, we are able to obtain an overall estimate of the probability that the two p levels might have been obtained if there truly were no relationship between the variables X and Y. We will present here the simplest and most versatile procedure combining probability levels, the method of adding Z's called the Stouffer method (Mosteller & Bush, 1954); other methods are summarized elsewhere (Rosenthal, 1978, 1991).

Like the method for comparing p values, the first step is to obtain accurate p levels for each of the two studies and then to find the Z's corresponding to those p's. The following equation is then applied:

$$\frac{Z_1 + Z_2}{\sqrt{2}} = Z \qquad (4)$$

Example 4

Studies A and B yield results in the same direction but neither are significant. One p value is 0.10, the other is 0.15, with corresponding Z's of 1.28 and 1.04. From Equation (4), we have

$$\frac{Z_1 + Z_2}{\sqrt{2}} = \frac{1.28 + 1.04}{\sqrt{2}} = 1.65$$

the p associated with this Z is 0.05. Thus, we have an example of two studies, neither of which yielded significant results when considered individually but which were significant when meta-analytically combined.

Example 5

The results of Studies A and B are in opposite directions and are both significant. One p is 0.00001, one-tailed, and the other is 0.03, one-tailed, but in the opposite direction. The Z's corresponding to these p's are 4.26 and -1.88 (note the opposite signs indicate results in opposite directions). Using Equation (4), we have

$$\frac{(4.26) + (-1.88)}{\sqrt{2}} = 1.68$$

with an associated p of 0.046. Thus, the combined p supports the finding of the more significant of the two results. However, since the two p's were so significantly different, we should be cautious in our interpretation and should search for that factors may have led Studies A and B to have obtained such different results.

3.15.4.2.2 Effect size estimation

Once we have computed the associated Fisher z_r's for each r, the combined effect size estimate is simply

$$\frac{z_{r_1} - z_{r_2}}{2} = \bar{z}_{r_1} \qquad (5)$$

or the Fisher z_r corresponding to our mean r. We can then look up the r associated with this mean z_r (using an r to z_r or z_r to r table or statistical software).

Example 6

Studies A and B yield results in the same direction, one $r = 0.95$, the other $r = 0.25$. The Fisher z_r's corresponding to these r's are 1.83 and 0.26, respectively. Applying Equation 5, we have

$$\frac{z_{r_1} + z_{r_2}}{2} = \frac{1.83 + 0.26}{2} = 1.045$$

which is our mean Fisher z_r. This value can then be converted back to an r of 0.78 which can be interpreted as showing a rather large combined mean effect (Cohen, 1977, 1988) from these two studies.

Example 7

Study A and B yield effect sizes of $r = 0.30$ and 0.00 respectively. The Fisher z_r's corresponding to these two effect sizes are 0.31 and 0.00. Again applying Equation (5) we have

$$\frac{0.31 + 0.00}{2} = 0.155$$

as our mean z_r which is associated with a mean r of 0.15.

These last two examples also illustrate that the use of Fisher's z_r gives heavier weight to r's that are further from zero in either direction but makes little difference when working with very small r's. If we had averaged the two r's from Example 6 without first transforming them to Fisher z_r's, we would have found a mean r of $(0.95 + 0.25)/2 = 0.60$, substantially smaller than the 0.78 which we found using the Fisher z_r's. However, if we recompute Example 7 using r's instead of Fisher z_r's, we would obtain the same result: $(0.30 + 0.00)/2 = 0.15$.

3.15.4.3 Comparing Three or More Studies: Diffuse Test

The following procedures are generalizations of the procedures just described which can be used to compare more than two studies. As mentioned earlier, when dealing with three or more studies, we are able to conduct both diffuse comparisons as well as focused comparisons. We will begin with the procedures for diffuse tests.

3.15.4.3.1 Significance testing

As with two studies, the first step is to find the Z associated with each p level. The studies can then be compared using the following equation:

$$\sum(Z_j - \bar{Z})^2 = \chi^2 \tag{6}$$

which is distributed as chi-square with $K - 1$ *df*. In this equation, Z_j is the Z for any one study, $\bar{Z}$ is the mean of all the Z's obtained, and K is the number of studies being compared. A significant chi-square tells us that the p's associated with our studies differ significantly among themselves.

Example 8

Studies A, B, C, and D yield one-tailed p values of 0.05, 0.001, 0.17, and 0.01, respectively. However, Study C shows results in the opposite direction from Studies A, B, and D. We find the Z's corresponding to these p's to be 1.64, 3.09, -0.95, and 2.33 (note the negative sign for Study C whose results were in the opposite direction). Using Equation (6) we find a chi-square value of

$$\sum(Z_j - \bar{Z})^2 = [(1.64) - (1.53)]^2 + [(3.09) - (1.53)]^2 + [(-0.95) - (1.53)]^2 + [(2.33) - (1.53)]^2 = 9.24$$

which for $K - 1 = 3$ *df* is significant at $p = 0.03$. The p values from these four studies, then, are significantly heterogeneous.

3.15.4.3.2 Effect size estimation

The statistical significance of the heterogeneity of the effect sizes of three or more studies is also obtained from a chi-square using the following equation

$$\sum(n_j - 3)(z_{r_1} - \bar{z}_r)^2 = \chi^2 \tag{7}$$

where n is the number of sampling units on which each r is based, z_{rj} is the Fisher z_r corresponding to each r, and $\bar{z}_r$ is the weighted mean z_r, that is

$$\bar{z}_r = \frac{\sum(n_j - 3)z_{r_j}}{\sum(n_j - 3)} \tag{8}$$

Example 9

Studies A, B, C, and D yield effect sizes of $r = 0.70$ ($n = 30$), $r = 0.45$ ($n = 45$), $r = 0.10$ ($n = 20$), and $r = -0.15$ ($n = 25$), respectively. The Fisher z_r's corresponding to these r's are 0.87, 0.48, 0.10, -0.15. First, using Equation (8), the weighted mean, z_r, is

$$\frac{[27(0.87) + 42(0.48) + 17(0.10) + 27(-0.15)]}{27 + 42 + 17 + 22} = 0.39$$

Then, applying Equation (7), we find that

$$27(0.87 - 0.39)_2 + 42(0.48 - 0.39)_2 + 17(0.10 - 0.39)_2 + 22(-0.15 - 0.39)^2 = 14.4$$

which for $K - 1 = 3$ *df* is significant at $p = 0.0024$. These four effect sizes, then, are significantly heterogeneous.

3.15.4.3.3 Comparing three or more studies: focused tests

While the two examples above showed us that the set of four studies were found to be significantly heterogeneous both in terms of their significance levels and effect sizes, they merely told us that overall the four studies differed. It is generally more useful to have more focused information about how the four studies differed. For example, did the prescribed treatment differ when given to women vs. men? Or, for example, did the studies in which the subjects lived in nursing homes differ from those studies in which the subjects lived with their families? In order to answer this question, it is necessary to conduct focused tests, also known as contrasts.

3.15.4.3.4 Significance levels

As with the diffuse comparisons, we first find the Z's that correspond to the p level of each study. We then compute a Z from the following equation

$$\frac{\sum \lambda_j Z_j}{\sqrt{\sum \lambda_j^2}} = Z \tag{9}$$

In this equation λ_j is the theoretically derived prediction or contrast weight for any one study, chosen such that the sum of the λ_j's will be zero. Z_j is the Z for any one study.

Example 10

Studies A, B, C, and D were conducted to examine the efficacy of a new type of behavioral therapy. They yielded the following one-tailed p values: 0.0001, 0.03, 0.15, and 0.10, all in the same direction. We calculate the Z's corresponding to these p's to be 3.72, 1.88, 1.04, and 1.28, respectively. We also know that the amount of therapy given in each of the studies differed such that Studies A, B, C, and D involved 8, 6, 4, and 2 h of therapy per month, respectively. A focused question that would be of interest to us in this example might be whether there was a significant linear relationship between the number of hours of therapy and the statistical significance of the result. The weights of a linear contrast involving four studies are 3, 1, -1, -3, as obtained from a table of orthogonal polynomials (e.g., Rosenthal & Rosnow, 1991). Therefore, from Equation (9) we have

$$\frac{\sum \lambda_j Z_j}{\sqrt{\sum \lambda_j^2}} = \frac{(3)3.72 + (1)1.88 + (-1)1.04 + (-3)1.28}{\sqrt{(3)^2 + (1)^2 + (-1)^2 + (-3)^2}} = 1.82$$

as our Z value which is significant at $p = 0.03$. Thus, the four p values tend to grow more significant as more hours of therapy are received per month.

3.15.4.3.5 Effect size estimation

It is almost always quite valuable to the researcher to compute a focused comparison on a series of effect sizes. For example, given a set of effect sizes for studies of a new behavioral therapy, we might want to know whether these effects are increasing or decreasing linearly with the number of hours of therapy received per month. It is from the focused comparison of effects that we are able to test moderator variables and often form new theories.

As was the case for diffuse tests, we begin by computing the effect size r, its associated Fisher z_r and $n-3$ where n is the number of sampling units on which each r is based. The statistical significance of the focused test or contrast then is obtained from a Z computed as follows (Rosenthal & Rubin, 1982a):

$$\frac{\sum \lambda_j z_{r_j}}{\sqrt{\frac{\sum \lambda_j^2}{W_j}}} = Z \qquad (10)$$

Once again, λ_j is the theoretically derived prediction or contrast weight for any one study, chosen such that the sum of the λ_j's will be zero. The z_{rj} is the Fisher z_r for any one study and w_j is the inverse of the variance of the effect size for each study. When using Fisher z_r transformations of the effect size r, the variance is $1/(n_j - 3)$, so for the present example, $w_j = n_j - 3$.
Example 11

Studies A, B, C, and D yield effect sizes of 0.89, 0.76, 0.23, and 0.59, respectively, all with $n = 12$. The Fisher z_r's corresponding to these r's are found to be 1.42, 1.00, 0.23, and 0.68, respectively. We also know that Studies A, B, C, and D involved 8, 6, 4, and 2 h of therapy per month, respectively. We are interested in whether there is a relationship between number of hours of therapy received and size of observed effect favoring the new therapy. As in Example 10, the appropriate λ's are 3, 1, -1, and -3. Therefore, applying Equation (10) we find

$$\frac{\sum \lambda_j z_{r_j}}{\sqrt{\frac{\sum \lambda_j^2}{W_j}}} = \frac{(3)1.42 + (1)1.00 + (-1)0.23 + (-3)0.68}{\sqrt{\frac{(3)^2}{9} + \frac{(1)^2}{9} + \frac{(-1)^2}{9} + \frac{(-3)^2}{9}}} = 2.01$$

as our Z value which is significant at $p = 0.22$. Thus, the four effect sizes tend to grow larger as the number of hours of therapy increases.

(i) Interpretation of moderator variables

Examples 10 and 11 seem to show that number of hours of therapy is linked linearly to effectiveness of the therapy. Yet, in these hypothetical examples, subjects were not assigned at random to the four studies, each of which studied the effects of treatment employing a different number of hours per week of therapy. Therefore, our interpretation of this finding must be cautious. We cannot be sure that differences between the four studies are due to the different number of therapy hours and not to some other variable that is also correlated with this moderator. The finding should not be taken as evidence for a causal relationship, rather as being suggestive of the possibility of a causal relationship, a possibility which can then be studied experimental in future research (Hall, Tickle-Degnen, Rosenthal, & Mosteller, 1994).

3.15.4.4 Combining Three or More Studies

3.15.4.4.1 Significance testing

By combining the p levels of a set of studies, we are able to obtain an overall estimate of the probability that the set of p levels might have been obtained if the null hypothesis of no relationship between X and Y were true. The method presented here is the generalized version of the method presented earlier as applying to the results of two studies; other methods are described in detail elsewhere (e.g., Rosenthal, 1991).

As before, we first obtain the Z's corresponding to our p levels (with Z's disagreeing in direction given negative signs). The sum of the Z's is then divided by the square root of the number of studies (K) yielding a new statistic which is distributed as Z, as follows:

$$\frac{\sum Z_j}{\sqrt{k}} = Z \tag{11}$$

Example 12

Studies A, B, C, and D yield one-tailed p values of 0.05, 0.001, 0.17, and 0.01, respectively. However, Study C shows results in the opposite direction from Studies A, B, and D. We find the Z's corresponding to these p's to be 1.64, 3.09, -0.95, and 2.33 (note the negative sign for Study C whose results were in the opposite direction). Applying Equation (11) we then find:

$$\frac{\sum Z_j}{\sqrt{k}} = \frac{(1.64) + (3.09) + (-0.95) + (2.33)}{\sqrt{4}}$$
$$= 3.06$$

as our new Z value which is associated with a p of 0.001, one-tailed. (We would normally use a one-tailed p if we had correctly predicted the bulk of the findings but would use a two-tailed p value if we had not.) Thus, we find a combined p level for the four studies that would be highly unlikely if the null hypothesis were true. Yet, we should be very cautious about drawing any simple overall conclusion from this combined significance level because of the heterogeneity of these four p levels. Example 8 employed the same p values and found that they were significantly different at $p = 0.03$. This heterogeneity, however, could be due to heterogeneity of effect sizes, of sample sizes, or both. We should always look carefully at the effect sizes and sample sizes of the studies before drawing any conclusions based on the significance levels above.

3.15.4.4.2 Effect size estimation

When combining the results of three or more studies, we are at least as interested in the combined effect size estimate as in the combined probability discussed above. In computing this value, we once again convert our r's to the associated Fisher z_r's and simply find the mean Fisher z_r as follows:

$$\frac{\sum z_r}{k} = \bar{z}_r \tag{12}$$

where K refers to the number of studies being combined. We then find the r associated with this mean z_r.

Example 13

Studies A, B, and C yield effect sizes of $r = 0.70$, 0.45, and 0.10, respectively, all in the same direction. The Fisher z_r values associated with these r's are 0.87, 0.48, and 0.10, respectively. Applying Equation (12), we find

$$\frac{\sum z_r}{k} = \frac{0.87 + 0.48 + 0.10}{3} = 0.48$$

as our mean Fisher z_r, which corresponds to an r of 0.45, a rather strong combined effect of the three studies. In this example, all the effect sizes were in the same direction; however, if we had a case of three studies where effect sizes seemed to be substantially heterogeneous, we would be cautious in our interpretation of the combined effect size, just as we were in our treatment of the combined probabilities in Example (12).

3.15.4.5 Weighting Studies

When combining two or more studies, the meta-analyst may choose to weight each study by size of study (*df*), estimated quality of study, or any other desired weights (Mosteller & Bush, 1954; Rosenthal, 1978, 1980, 1984). The general procedure for weighting Z's is to (i) first assign to each study a given weight (symbolized by w and which is assigned before inspection of the data); (ii) multiply each Z by the desired weight, w; (iii) add the weighted Z's and; (iv) divide this sum by the square root of the sum of the squared weights, as follows:

$$\frac{\sum w_j Z_j}{\sqrt{\sum w_j^2}} = Z_w \tag{13}$$

Example 14

We are interested in finding the combined Z from the four studies discussed in Example 12 and now we want to weight them each by their degrees of freedom which are 24, 75, 4, and 50, respectively. From Example 12, we found Z's for the four studies to be 1.64, 3.09, -0.95, and 2.33. Applying Equation (13) we now find:

$$\frac{\sum w_j z_j}{\sqrt{\sum w_j^2}}$$
$$= \frac{24(1.64) + 75(3.09) + 4(-0.95) + 50(2.33)}{\sqrt{(24)^2 + (75)^2 + (4)^2 + (50)^2}}$$
$$= 4.11$$

as our combined Z which is associated with a p of 0.00002. We should keep in mind that when weighting Z's by *df*, the size of the study is actually playing a doubly large role since it has already been entered into the determination of each Z initially.

We can similarly weight effect sizes by *df* or any other desired weight using the following equation:

$$\bar{z}_{r_{weighted}} = \frac{\sum w_j z_{r_j}}{\sqrt{\sum w_j}} \tag{14}$$

Example 15

From Example 13, we found that Studies A, B, and C yield Fisher z_r values of 0.87, 0.48, and 0.10, respectively. The *df*'s for each study are 56, 120, and 24, respectively. Applying Equation (14), we find:

$$\begin{aligned}\bar{z}_{r_{weighted}} &= \frac{\sum w_j z_{r_j}}{\sqrt{\sum w_j}} \\ &= \frac{56(0.87) + 120(0.48) + 24(0.10)}{56 + 120 + 24} \\ &= 0.54\end{aligned}$$

as our mean weighted Fisher z_r which corresponds to an r of 0.49, slightly larger than the unweighted mean effect size r of 0.45 which we found above.

3.15.5 SPECIAL CASES

3.15.5.1 Imprecisely Reported *p*'s

The meta-analytic procedures discussed above for combining and comparing significance levels require the meta-analyst to find the Z associated with the given p from each study. Unfortunately, it is quite common for p's to be reported imprecisely as $p < 0.05$ or < 0.01 so that p might be 0.001 or 0.0001 or even 0.00001. When this is the case, the researcher needs to go back to the original test statistic employed, for example, t, F, Z, or chi-square, which many journals require their contributors to report. The *df* for the t and for the denominator of the F test tell us about the size of the study. The *df* for chi-square is analogous to the *df* for the numerator of the F test and so tells us about the number of conditions, not the number of sampling units. Fortunately, the 1983 edition of the Publication Manual of the American Psychological Association has added the requirement that the total N be reported together with the *df* for conditions for chi-square tests. Using the reported test statistic and the information about the size of the study, we should be able to obtain the exact p value for the given test statistic and the Z associated with that p.

Occasionally, we may have information about an effect size estimator (such as r, d, or g) but not a test statistic. Using the equations in section 3.15.4.1.2 we can often derive the associated test statistic, its exact p value, and the associated Z.

If a result is simply reported as "nonsignificant," and if no further information is available, we have little choice but to treat the result as a p of 0.50, which corresponds to a Z of 0.00. Although this procedure is ordinarily conservative leading to effect size estimates that are too small, the alternative of not using those studies is likely to lead to effect size estimates that are too large and almost surely to p values that are too significant. The recommended approach is to conduct the analysis both ways—with the studies and without the studies and to see how much of a difference it will make to the overall view of the data.

3.15.5.2 Repeated Measures Designs

A recent meta-analysis (Kramer & Rosenthal, 1997) introduced the concept of the repeated measures meta-analysis. In this situation, the question of interest concerns the difference between two or more effect sizes for each study. The meta-analysis compared the improvement in problem-solving performance when individuals were formed into noninteracting groups vs. their performance when they actually interacted as a group. A similar situation where one may be interested in a repeated measures question might be where patients' improvement is first measured one month after receiving a new treatment and this improvement is then compared to their improvement a year after receiving the treatment. One useful way to approach this type of meta-analysis is to treat it as if it were two meta-analyses whose results are then compared. In the first example above, a meta-analysis was conducted of the effect sizes associated with improvement from the individual to the noninteracting group condition. The results from this meta-analysis were then compared with the meta-analytic results of the size of the effect associated with improvement due to interaction.

3.15.5.3 Random vs. Fixed Effects

A common area of confusion is the distinction between random and fixed effects models of analysis. The fixed effects model is in the same spirit as a regression model or a fixed analysis of variance in which the treatment levels are considered fixed and the random variation is from the sample of individuals within treatment levels. With a fixed effects analysis, we are able to generalize to participants of the type found in the studies we included in the meta-analysis but we are not able to generalize to other studies.

This is because the source of sampling error in the fixed model is the variation among the people in the studies. Although our generalizability is somewhat restricted by using a fixed effects model, we gain in statistical power because our *df* are drawn from the total *N* of all the studies.

With a random effects model, our generalizability increases to all studies of the type from which our sample of studies was drawn. However, by employing a random effects model, we lose in statistical power compared to the fixed effects analysis. A simple one-sample *t*-test on the mean effect size (Mosteller & Bush, 1954) is often an appropriate random effects analysis. It will typically be more conservative than the results of the Stouffer method, but would allow for more generalizability. It is highly recommended to conduct an analysis both with a random and a fixed effects model and to compare the two methods. (For more detailed discussion of these issues, see Hedges, 1994; Raudenbush, 1994; Rosenthal, 1995a; Shadish & Haddock, 1994).

3.15.6 CRITICISMS OF META-ANALYSIS

3.15.6.1 Sampling Bias and the File Drawer Problem

One of the most frequent criticisms leveled against meta-analyses is that they are inherently biased because there is a greater likelihood that published studies will have significant results and thus might not be representative of the population of studies which have been conducted. This criticism, while well taken, could equally well be applied to narrative reviews of the literature. However, with a meta-analysis, there are now certain computational procedures that can be employed to address this problem. One visual way of examining the issue of publication bias is through the use of a Funnel Plot (Light & Pillemer, 1984), a scatterplot of sample size vs. estimated effect sizes. Another method is to compute a "file drawer analysis" (Rosenthal, 1991; Rosenthal & Rubin, 1988) as follows.

To find the number (*X*) of new, filed, or unretrieved studies averaging null results required to bring the new overall *p* to any desired level of significance (e.g., $p = 0.05$, $Z = 1.645$), the following equation may be used:

$$X = \frac{(\sum Z)^2}{2.706} - k \qquad (15)$$

where *K* is the number of studies combined and ΣZ is the sum of the *Z*'s obtained for the *K* studies.

Example 16

57 experiments have been conducted examining the effect of a new treatment for alcoholism. The ΣZ of these 57 studies was 98.6. How many new, filed, or unretrieved studies (*X*) would be required to bring this *Z* down to a barely significant level ($Z = 1.645$)? From Equation (15) we have

$$X = \frac{(98.6)^2}{2.706} - 57 = 3535$$

Thus, there would need to be over 3000 studies averaging null results tucked away in file drawers before one could conclude that the overall results of the 57 experiments were due to sampling bias.

3.15.6.2 Combining Apples and Oranges: Problems of Heterogeneity

Meta-analysis has been criticized for combining apples and oranges, in other words, for combining studies with different operationalizations of independent and dependent variables and different sampling units. This is in fact true, and a good meta-analysis will examine these differing factors as potential moderating variables as was discussed above.

Critics of meta-analysis have also pointed out the dangers of combining studies of different quality and treating them all as equal. This is an issue which can be dealt with by weighting studies according to their quality using the same procedures illustrated in Examples 14 and 15 where studies were weighted by study size. Consider the following example.

Example 17

Studies A, B, and C yield effect sizes of Fisher $z_r = 0.70$, 0.23, and 0.37. A group of judges rated these three studies for their internal validity and found mean ratings of 1.5, 3.4, and 4.0. Using these mean ratings as weights, the weighted combined effect size can be calculated using Equation (14):

$$\frac{\sum w_j z_{r_j}}{\sum w_j} = \frac{1.5(0.70) + 3.4(0.23) + 4.0(3.7)}{1.5 + 3.4 + 4.0}$$
$$= 0.37$$

We can conclude that weighting by quality of research in this case led to a somewhat different result than not weighting in that it lowered the perhaps somewhat elevated effect size of the poorer quality study.

Coding of studies for their quality involves having raters check each study for the presence of certain aspects, such as random assignment, experimenter blind to hypothesis, presence of demand characteristics, etc. and then adding the number of desirable features present for each study. Ratings of studies involves having raters make a more global, overall assessment of the methodological quality of a study. When establishing weightings of quality, the coding or rating should be done, as in hypothetical Example 17, by a group of disinterested judges, rather than by the researchers conducting the meta-analysis. This will safeguard against the understandable tendency to think of our own studies, of those of our students and our friends, and of those who successfully replicate our work as good studies while thinking of those studies conducted by our enemies and by those who failed to replicate our work as bad studies. Reliability of coding or rating should also be reported.

3.15.6.3 Problems of Independence

3.15.6.3.1 Nonindependence of subjects

It would not be unusual for the meta-analyst to discover multiple studies in which the same subjects have participated or that within one study subjects have contributed to more than one dependent variable. For example, a study may present the assessments of a group of subjects on a number of different measures of sensitivity to nonverbal cues. In this situation, the results generated by each dependent variable (each measure of nonverbal sensitivity) cannot be considered independent of each other since the same subjects contributed toward each one. Although it would be an error to treat multiple results from one study as though they were independent for significance testing, there is nothing wrong in doing so for the purposes of effect size estimation. By doing so, the researcher weights each study in proportion to the number of different effect sizes it generates, a procedure which meta-analysts might not choose to do but one which would not be unjustifiably wrong. Our recommendation is to use any of the procedures mentioned in order to produce only one effect size estimate and significance level for each study for the overall analysis. One option for combining the various significance levels and effect sizes would simply be to take the mean or the median Z or z_r of all the dependent variables. (The mean Z could be computed by averaging the Z's or by first averaging the z_r's and then getting the Z associated with the mean z_r; the mean z_r could also be computed by averaging the p levels and then computing the effect size that corresponds to that mean p level. These different procedures can yield different results, none of which is intrinsically more correct, but one should be chosen beforehand and used consistently through out the meta-analysis.)

However, unless the dependent variables are perfectly correlated, using the mean or the median estimates is likely to be somewhat conservative. If the meta-analyst has available the degrees of freedom and typical intercorrelation among the dependent variables, another approach, described in more detail elsewhere (Rosenthal & Rubin, 1986), can provide a more accurate combination of the effect sizes which can then be entered into the meta-analysis. This approach also allows the meta-analyst to compute contrasts among the effect sizes for the multiple dependent variables.

3.15.6.3.2 Nonindependence of experimenters

Given that researchers within the same laboratory or who once worked within the same laboratory group may have similar interests, it quite frequently occurs that several of the studies in the meta-analysis have been conducted by the same experimenter or experimental team. This may be problematic in that the results of researcher A may be correlated with those of researcher B despite the fact that they used different participants. It would be sound practice to analyze the studies by laboratory as well as by study. For example, a recent meta-analysis of the predictive power of short samples of nonverbal behavior (Ambady & Rosenthal, 1992) compared studies authored by either of the two meta-analysts to studies conducted by other researchers. The comparison showed all the effect sizes to be quite homogenous with a mean effect size of studies by the two researchers of $r = 0.38$ compared to a mean r of 0.39 by the others.

3.15.6.4 Exaggerated Significance Levels

The "criticism" that meta-analyses yield more significant results is to a great extent true. As we saw with Equation(1) (Significance Test = Size of Effect × Size of Study), as more subjects are added, either to a single study or to a meta-analysis of many studies, the results will become more significant. In fact, this is one of the benefits of conducting meta-analyses in that it allows for the cumulation of knowledge that was discussed above so that we no longer dismiss studies which have not found p's < 0.05 but rather cumulate them so that the body of work may show its overall significance level and effect size.

3.15.6.5 Too Small Effects

In contrast to the argument above, another criticism of meta-analysis is that the results of

Table 6 A binomial effect size display (BESD) of the relationship between aspirin usage and heart attacks.

	Heart attack	*No heart attack*	*Total*
Aspirin	48.3	51.7	100
Placebo	51.7	48.3	100
Total	100	100	200

some meta-analyses really only show "small effects" because the obtained *r*'s and subsequent *r*'s are small. While this may be true, it is also true that small effects can have great importance. A classic example of this is the Physician's Aspirin Study (see Rosenthal, 1995b). In 1988, a study of the effects of aspirin on reducing heart attacks was prematurely terminated. It had become clear to the physicians involved that it would be unethical to continue to give half of the subjects a placebo, since aspirin clearly prevented heart attacks. What was the *r* of this study? The *r* was 0.034, with an r^2 of 0.0011.

Table 6 presents the results of the aspirin study as a Binomial Effect Size Display (BESD), a display which allows us to see the practical importance of the effect (Rosenthal & Rubin, 1982b). The correlation is shown as the difference in outcome rates between the experimental and the control group. As the BESD shows, aspririn lead to a 4% decrease in heart attacks, a small but rather important, effect.

3.15.6.6 Abandonment of Primary Studies

Finally, critics have claimed that the growing use of meta-analysis has destroyed the motivation (or even the need) to conduct primary research studies. Certainly not: first of all, the primary studies are needed in order to do a meta-analysis. Second, the research suggested by meta-analyses can only be addressed by newly designed primary studies employing randomization. A great benefit of meta-analysis is that it will prevent unnecessary duplication, replication, and the wasting of scientifically and socially valuable resources. Conducting more meta-analyses may very well reduce the number of primary studies conducted, but it should increase the potential value of those that are conducted.

4.01.1 INTRODUCTION

In this chapter we will describe the current state of affairs with respect to assessment in clinical psychology and then we will attempt to show how clinical psychology got to that state, both in terms of positive influences on the directions that efforts in assessment have taken and in terms of missed opportunities for alternative developments that might have been more productive psychology. For one thing, we really do not think the history is particularly interesting in its own right. The account and views that we will give here are our own; we are not taking a neutral—and innocuous—position. Readers will not find a great deal of equivocation, not much in the way of "a glass half-empty is, after all, half-full" type of placation. By assessment in this chapter, we refer to formal assessment procedures, activities that can be named, described, delimited, and so on. We assume that all clinical psychologists are more or less continuously engaged in informal assessment of clients with whom they work. Informal assessment, however, does not follow any particular pattern, involves no rules for its conduct, and is not set off in any way from other clinical activities. We have in mind assessment procedures that would be readily defined as such, that can be studied systematically, and whose value can be quantified. We will not be taking account of neuropsychological assessment nor of behavioral assessment, both of which are covered in other chapters in this volume. It will help, we think, if we begin by noting the limits within which our critique of clinical assessment is meant to apply. We, ourselves, are regularly engaged in assessment activities, including developmemt of new measures, and we are clinicians, too.

4.01.1.1 Useful Clinical Assessment is Difficult but not Impossible

Many of the comments about clinical assessment that follow may seem to some readers to be pessimistic and at odds with the experiences of professional clinicians. We think our views are quite in accord with both research and the theoretical underpinnings for assessment activities, but in at least some respects we are not so negative in our outlook as we may seem. Let us explain. In general, tests and related instruments are devised to measure constructs, for example, intelligence, ego strength, anxiety, antisocial tendencies. In that context, it is reasonable to focus on the construct validity of the test at hand: how well does the test measure the construct it is intended to measure? Generally speaking, evaluations of tests for construct validity do not produce single quantitated indexes. Rather, evidence for construct validity consists of a "web of evidence" that fits together at least reasonably well and that persuades a test user that the test does, in fact, measure the construct at least passably well. The clinician examiner especially if he or she is acquainted in other ways with the examinee, may form impressions, perhaps compelling, of the validity of test results. The situation may be something like the following:

Test <—construct

That is, the clinician uses a test that is a measure of a construct. The path coefficient relating the test to the construct (in the convention of structural equations modeling, the construct causes the test performance) may well be substantial. A more concrete example is provided by the following diagram:

IQ Test <—0.80—intelligence

This diagram indicates that the construct of intelligence causes performance on an IQ test. We believe that IQ tests may actually be quite good measures of the construct of "intelligence." Probably clinicians who give intelligence tests believe that in most instances the test gives them a pretty good estimate of what we mean by intelligence, for example, 0.80 in this example. To use a term that will be invoked later, the clinician is "enlightened" by the results from the test.

As long as the clinical use of tests is confined to enlightenment about constructs, many tests may have reasonably good, maybe even very good "validity." The tests are good measures of the constructs. In many, if not most, clinical uses of tests, however, the tests are used in order to make decisions. Tests are used, for example to decide whether a parent should have custody of a child, to decide whether a patient is likely to benefit from some form of therapy, to decide whether a child "should" be placed in a social classroom, or to decide whether a patient should be put on some particular medication. Using our IQ test example, we get a diagram of the following sort:

IQ Test<—0.80—intelligence—0.50—> School grades

This diagram, which represents prediction rather than simply enlightenment, has two paths, and the second path is almost certain to have a far lower validity coefficient than the first one. Intelligence has a stronger relationship to performance on an IQ test than to performance in school. If an IQ test had construct validity of 0.80, and if intelligence as a construct were correlated 0.50 with school grades, which means that intelligence would account for 25% of the total variance in school grades, then the correlation between the IQ test and school grades would be only 0.80 x 0.50 = 0.40 (which is about what is generallly found to be the case).

IQ Test<—0.40—>School grades

A very good measure of ego strength may not be a terribly good predictor of resistance to stress in some particular set of circumstances. Epstein (1983) pointed out some time ago that tests cannot be expected to be related especially well to specific behaviors, but it is in relation to specific behaviors that tests are likely to be used in clinical settings.

It could be argued and has been, (e.g., Meyer & Handler 1997), that even modest validities like 0.40 are important. Measures with a validity of 0.40, for example, can improve ones prediction from that 50% of a group of persons will succeed at some task to the prediction that 70% will succeed. If the provider of a service cannot serve all eligible or needy persons, that improvement in prediction may be quite useful.

In clinical settings, however, decisions are made about individuals, not groups. To recommend that one person should not receive a service because the chances of benefit from the service are only 30% instead of the 50% that would be predicted without a test, could be regarded as a rather bold decision for a clinician to make about a person in need of help. Hunter and Schmidt (1990) have developed very useful approaches to validity generalization that usually result in estimates of test validity well above the correlations reported in actual use, but their estimates apply at the level of theory, construct validity, rather than at the level of specific application as in clinical settings.

A recommendation to improve the clinical uses of tests can actually be made: test for more things. Think of the determinants of performance in school, say college, as an example. College grades depend on motivation, persistence, physical health, mental health, study habits, and so on. If clinical psychologists are serious about predicting performance in college, then they probably will need to measure several quite different constructs and then combine all those measures into a prediction equation. The measurement task may seem onerous, but it is worth remembering Cronbach's (1960) band width vs. fidelity argument: it is often better to measure more things less well than to measure one thing extraordinarily well. A lot of measurement could be squeezed into the times usually allotted to low bandwidth tests. The genius of the profession will come in the determination of what to measure and how to measure it. The combination of all the information, however, is likely best to be done by a statistical algorithm for reasons that we will show later.

We are not negative toward psychological testing, but we think it is a lot more difficult and complicated than it is generally taken to be in practice. An illustrative case is provided by the differential diagnosis of attention deficit hyperactivity disorder (ADHD). There might be an ADHD scale somewhere but a more responsible clinical study would recognize that the diagnosis can be difficult, and that the validity and certainty of the diagnosis of ADHD is greatly improved by using multiple measures and multiple reporting agents across multiple contexts. For example, one authority recommended beginning with an initial screening interview, in which the possibility of an ADHD diagnosis is ruled in, followed by an extensive assessment battery addressing multiple domains and usually including (depending upon age): a Wechsler Intelligence Scale for Children (WISC-III; McCraken & McCallum, 1993), a behavior checklist (e.g., Youth Self-Report (YSR); Achenbach & Edelbrock, 1987), an academic achievement battery (e.g., Kaufmann Assessment Battery for Children; Kaufmann & Kaufmann, 1985), a personality inventory (e.g., Millon Adolescent Personality Inventory (MAPI); Millon & Davis, 1993), a computerized sustained attention and distractibility test (Gordon Diagnostic System [GDS]; McClure & Gordon, 1984), and a semistructured or a stuctured clinical interview (e.g., Diagnostic Interview Schedule for Children [DISC]; Costello, Edelbrock, Kalas, Kessler, & Klaric, 1982).

The results from the diagnostic assessment may be used to further rule in or rule out ADHD as a diagnosis, in conjunction with child behavior checklists (e.g., CBCL, Achenbach & Edelbrock, 1983; Teacher Rating Scales, Goyette, Conners, & Ulrich, 1978), completed by the parent(s) and teacher, and additonal school performance information. The parent and teacher complete both a historical list and then a daily behavior checklist for a period of two weeks in order to adequately sample behaviors. The information from home and school domains may be collected concurrently with evaluation of the diagnostic assessement battery, or the battery may be used initially to continue to rule in the diagnosis as a possibility, and then proceed with collateral data collection. We are impressed with the recommended ADHD diagnostic process, but we do recognize that it would involve a very extensive clinical process that would probably not be reimbursable under most health insurance plans. We would also note, however, that the overall diagnostic approach is not based on any decision-theoretic approach that might guide the choice of instruments corresponding to a process of decision making. Or alternatively, the process is not guided by any algorithm for combining information so as to produce a decision. Our belief is that assessment in clinical psychology needs the same sort of attention and systematic study as is occurring in medical areas through such organizations as the Society for Medical Decision Making.

In summary, we think the above scenario, or similar procedures using similar instruments (e.g., Atkins, Pelham, & White, 1990; Hoza, Vollano, & Pelham, 1995), represent an exemplar of assessment practice. It should be noted, however, that the development of such multimodal batteries is an iterative process. One will soon reach the point of diminishing returns in the development of such batteries, and the incremental validity (Sechrest, 1963) of instruments should be assessed. ADHD is an example in which the important domains of functioning are understood, and thus can be assessed. We know of no examples other that ADHD of such systematic approaches to assessment for decision making. Although approaches such as described here and by Pelham and his colleagues appear to be far from standard practice in the diagnosis of ADHD, we think they ought to be. The outlined procedure is modeled after a procedure developed by Gerald Peterson, Ph.D., Institute for Motivational Development, Bellevue, WA.

4.01.2 WHY ARE ASSESSMENTS DONE?

Why do we "test" in the first place? It is worth thinking about all the instances in which we do not test. For example, we usually do not test our own children—nor our spouses. That is because we have ample opportunities to observe the "performances" in which we are interested. That may be one reason that psychotherapists are disinclined to test their own clients: they have many opportunities to observe the behaviors in which they are interested, that is, if not the actual behaviors than reasonably good indicators of them. As we see it, testing is done primarily for one or more of three reasons: efficiency of observation, revealing cryptic conditions, and quantitative tagging.

Testing may provide for more efficient observation than most alternatives. For example, "tailing" a person, that method so dear to detective story writers, would prove definitive for many dispositions, but it would be expensive and often impractical or even unethical (Webb, Campbell, Schwartz, Sechrest, & Grove, 1981). Testing may provide for more efficient observation than most alternatives. It seems unlikely that any teacher would not have quite a good idea of the intelligence and personality of any of her pupils after at most a few weeks of a school year, but appropriate tests might provide useful information from the very first day. Probably clinicians involved in treating patients do not anticipate much gain in useful information after having held a few sessions with a patient. In fact, they may not anticipate much gain under most circumstances, which could account for the apparent infrequent use of assessment procedures in connection with psychological treatment.

Testing is also done in order to uncover "cryptic" conditions, that is, characteristics that are hidden from view or otherwise difficult to discern. In medicine, for example, a great many conditions are cryptic, blood pressure being one example. It can be made visible only by some device. Cryptic conditions have always been of great interest in clinical psychology, although their importance may have been exaggerated considerably. The Rorschach, a prime example of a putative decrypter, was hailed upon its introduction as "providing a window on the mind," and it was widely assumed that in skillful hands the Rorschach would make visible a wide range of hidden dispositions, even those unknown to the respondent (i.e., in "the unconscious"). Similarly, the Thematic Apperception Test was said to "expose underlying inhibited tendencies" of which the subject is unaware and to permit the subject to leave the test "happily unaware that he has presented the psychologist with what amounts to an X-ray picture of his inner self" (Murray, 1943, p. 1).

Finally, testing may be done, is often done, in order to provide a quantitative "tag" for some dispositions or other characteristic. In foot races, to take a mundane example, no necessity exists to time the races; it is sufficient to determine simply the order of the finish.

Nonetheless, races are timed so that each one may be quantitatively tagged for sorting and other uses, for example, making comparisons between races. Similarly, there is scarcely ever any need for more than a crude indicator of a child's intelligence, for example, "well above average," such as a teacher might provide. Nonetheless, the urge to seemingly precise quantification is strong, even if the precision is specious, and tests are used regularly to provide such estimates as "at the 78th percentile in aggression" or "IQ = 118." Although quantitative tags are used, and may be necessary, for some decision-making, for example, the awarding of scholarships based on SAT scores, it is to be doubted that such tags are ever of much use in clinical settings.

4.01.2.1 Bounded vs. Unbounded Inference and Prediction

Bounded prediction is the use of a test or measure to make some limited inference or prediction about an individual, couple, or family, a prediction that might be limited in time, situation, or range of behavior (Levy, 1963; Sechrest, 1968). Some familiar examples of bounded prediction are that of a college student's grade point average based on their SAT score, assessing the likely response of an individual to psychotherapy for depression based on MMPI scores and a SCID interview, or prognosticating outcome for a couple in marital therapy given their history. These predictions are bounded because they are using particular measures to predict a specified outcome in a given context. Limits to bounded predictions are primarily based on knowledge of two areas. First, the reliability of the information, that is, interview or test, for the population from which the individual is drawn. Second, and most important, these predictions are based on the relationship between the predictor and the outcome. That is to say, they are limited by the validity of the predictor for the particular context in question.

Unbounded inference or prediction, which is common in clinical practice, is the practice of making general assessment of an individual's tendencies, dispositions, and behavior, and inferring prognosis for situations that may not have been specified at the time of assessment. These are general statements made about individuals, couples, and families based on interviews, diagnostic tests, response to projective stimuli, and so forth that indicate how these people are likely to behave across situations. Some unbounded predictions are simply descriptive statements, for example, with respect to personality, from which at some future time the clinician or another person might make an inference about a behavior not even imagined at the time of the original assessment. A clinician might be asked to apply previously obtained assessment information to an individual's ability to work, ability as a parent, likelihood of behaving violently, or even the probability that an individual might have behaved in some way in the past (e.g., abused a spouse or child). Thus, they are unbounded in context. Since reliability and validity require context, that is, a measure is reliable in particular circumstances, one cannot readily estimate the reliability and validity of a measure for unspecified circumstances.

To the extent that the same measures are used repeatedly to make the same type of prediction or judgment about individuals, the more the prediction becomes of a bounded nature. Thus, an initially unbounded prediction becomes bounded by the consistency of circumstances of repeated use. Under these circumstances, reliability, utility, and validity can be assessed in a standard manner (Sechrest, 1968). Without empirical data, unbounded predictions rest solely upon the judgment of the clinician, which has proven problematic (see Dawes, Faust, & Meehl, 1989; Grove & Meehl, 1996; Meehl, 1954). Again, the contrast with medical testing is instructive. In medicine, tests are generally associated with gathering additional information about specific problems or systems. Although one might have a "wellness" visit to detect level of functioning and signs of potential problems, it would be scandalous to have a battery of medical tests to "see how your health might be" under an unspecified set of circumstances. Medical tests are bounded. They are for specific purposes at specific times.

4.01.2.2 Prevalence and Incidence of Assessment

It is interesting to speculate about how much assessment is actually done in clinical psychology today. It is equally interesting to realize how little is known about how much assessment is done in clinical psychology today. What little is known has to do with "incidence" of assessment, and that only from the standpoint of the clinician and only in summary form. Clinical psychologists report that a modest amount of their time is taken up by assessment activities. The American Psychological Association's (APA's) Committee for the Advancement of Professional Practice (1996) conducted a survey in 1995 of licensed APA members. With a response rate of 33.8%, the survey suggested that psychologists spend about 14% of their time conducting assessments—roughly six or seven hours per week. The low response rate, which ought to be considered disgraceful in a profession that claims to survive by science, is indicative of the difficulties involved in getting useful information about the practice of psychology in almost any area. The response rate was described as "excellent" in the report of the survey. Other estimates converge on about the same proportion of time devoted to assessment (Wade & Baker, 1977; Watkins, 1991; Watkins, Campbell, Nieberding, & Hallmark, 1995). Using data across a sizable number of surveys over a considerable period of time, Watkins (1991) concludes that about 50–75% of clinical psychologists provide at least some assessment services. We will say more later about the relative frequency of use of specific assessment procedures, but Watkins et al. (1995) did not find much difference in relative use across seven diverse work settings.

Think about what appears not to be known: the number of psychologists who do assessments in any period of time; the number of assessments that psychologists who do them actually do; the number or proportion of assessments that use particular assessment devices; the proportion of patients who are subjected to assessments; the problems for which assessments are done. And that does not exhaust the possible questions that might be asked. If, however, we take seriously the estimate that psychologists spend six or seven hours per week on assessment, then it is unlikely that those psychologists who do assessments could manage more than one or two per week; hence, only a very small minority of patients being seen by psychologists could be undergoing assessment. Wade and Baker (1977) found that psychologists claimed to be doing an average of about six objective tests and three projective tests per week, and that about a third of their clients were given at least one or the other of the tests, some maybe both. Those estimates do not make much sense in light of the overall estimate of only 15% of time (6–8 hours) spent in testing.

It is almost certain that those assessment activities in which psychologists do engage are carried out on persons who are referred by some other professional person or agency specifically for assessment. What evidence exists indicates that very little assessment is carried out by clinical psychologists on their own clients, either for diagnosis or for planning of treatment. Nor is there any likelihood that clinical psychologists refer their own clients to some other clinician for assessment. Some years ago, one of us (L. S.) began a study, never completed, of referrals made by clinical psychologists to other mental health professionals. The study was never completed in part because referrals were, apparently, very infrequent, mostly having to do with troublesome patients. A total of about 40 clinicians were queried, and in no instance did any of those clinical psychologists refer any client for psychological assessment.

Thus, we conclude that only a small minority of clients or patients of psychologists are subjected to any formal assessment procedures, a conclusion supported by Wade and Baker (1977) who found that relatively few clinicians appear to use standard methods of administration and scoring. Despite Wade and Baker's findings, it also seems likely that clinical psychologists do very little assessment on their own clients. Most assessments are almost certainly on referral. Now contrast that state of affairs with the practice of medicine: assessment is at the heart of medical practice. Scarcely a medical patient ever gets any substantial treatment without at least some assessment. Merely walking into a medical clinic virtually guarantees that body temperature and blood pressure will be measured. Any indication of a problem that is not completely obvious will result in further medical tests, including referral of patients from the primary care physician to other specialists.

The available evidence also suggests that psychologists do very little in the way of formal assessment of clients prior to therapy or other forms of intervention. For example, books on psychological assessment even in clinical psychology may not even mention psychotherapy or other interventions (e.g., see Maloney & Ward, 1976), and the venerated and authoritative *Handbook of psychotherapy and behavior change* (Bergen & Garfield, 1994) does not deal with assessment except in relation to diagnosis and the prediction of response to therapy and to determining the outcomes of therapy, that is, there is no mention of assessment for planning therapy at any stage in the process. That is, we think, anomalous, especially when one contemplates the assessment activities of other professions. It is almost impossible even to get to speak to a physician without at least having one's temperature and blood pressure measured, and once in the hands of a physician, almost all patients are likely to undergo further explicit assessment procedures, for example, auscultation of the lungs, heart, and carotid arteries. Unless the problem is completely obvious, patients are likely to undergo blood or other body-fluid tests, imaging procedures, assessments of functioning, and so on. The same contrast could be made for chiropractors, speech and hearing specialists, optometrists, and, probably, nearly all other clinical specialists. Clinical psychology appears to have no standard procedures, not much interest in them, and no instruments for carrying them out in any case. Why is that?

One reason, we suspect, is that clinical psychology has never shown much interest in normal functioning and, consequently, does not have very good capacity to identify normal responses or functioning. A competent specialist in internal medicine can usefully palpate a patient's liver, an organ he or she cannot see, because that specialist has been taught what a normal liver should feel like and what its dimensions should (approximately) be. A physician knows what normal respiratory sounds are. An optometrist certainly knows what constitutes normal vision and a normal eye. Presumably, a chiropractor knows a normal spine when he or she sees one.

Clinical psychology has no measures equivalent to body temperature and blood pressure, that is, quick, inexpensive screeners (vital signs) that can yield "normal" as a conclusion just as well as "abnormal." Moreover, clinical psychologists appear to have a substantial bias toward detection of psychopathology. The consequence is that clinical psychological assessment is not likely to provide a basis for a conclusion that a given person is "normal," and that no intervention is required. Obviously, the case is different for "intelligence," for which the conclusion of "average" or some such is quite common.

By their nature, psychological tests are not likely to offer many surprises. A medical test may reveal a completely unexpected condition of considerable clinical importance, for example, even in a person merely being subjected to a routine examination. Most persons who come to the attention of psychologists and other mental health professionals are there because their behavior has already betrayed important anomalies, either to themselves or to others. A clinical psychologist would be quite unlikely to administer an intelligence test to a successful business man and discover, completely unexpectedly, that the man was really "stupid." Tests are likely to be used only for further exploration or verification of problems already evident. If they are already evident, then the clinician managing the case may not see any particular need for further assessment.

A related reason that clinical psychologists appear to show so little inclination to do assessment of their own patients probably has to do with the countering inclination of clinical psychologists, and other similarly placed clinicians, to arrive at early judgments of patients based on initial impressions. Meehl (1960) noted that phenomenon many years ago, and it likely has not changed. Under those circumstances, testing of clients would have very little incremental value (Sechrest, 1963) and would seem unnecessary. At this point, it may be worth repeating that apparently no information is available on the specific questions for which psychologists make assessments when they do so.

Finally, we do believe that current limitations on practice imposed by managed care organizations are likely to limit even further the use of assessment procedures by psychologists. Pressures are toward very brief interventions, and that probably means even briefer assessments.

4.01.2.3 Proliferation of Assessment Devices

Clinical psychology has experienced an enormous proliferation of tests since the 1960s. We are referring here to commercially published tests, available for sale and for use in relation to clinical problems. For example, inspection of four current test catalogs indicates that there are at least a dozen different tests (scales, inventories, checklists, etc.) related to attention deficit disorder (ADD) alone, including forms of ADD that may not even exist, for example, adult ADD. One of the test catalogs is 100 pages, two are 176 pages, and the fourth is an enormous 276 pages. Even allowing for the fact that some catalog pages are taken up with advertisements for books and other such, the amount of test material available is astonishing. These are only four of perhaps a dozen or so catalogs we have in our files.

In the mid-1930s Buros published the first listings of psychological tests to help guide users in a variety of fields in choosing an appropriate assessment instrument. These early uncritical listings of tests developed into the *Mental measurements yearbook* and by 1937 the listings had expanded to include published test reviews. The *Yearbook*, which includes tests and reviews of new and revised tests published for commercial use, has continued to grow and is now in its 12th edition (1995). The most recent edition reviewed 418 tests available for use in education, psychology, business, and psychiatry. *Buros Mental Measurements Yearbook* is a valuable resource for testers, but it also charts the growth of assessment instruments. In addition to instruments published for commercial use, there are scores of other tests developed yearly for noncommercial use that are never reviewed by Buros. Currently, there are thousands of assessment instruments available for researchers and practitioners to choose from.

The burgeoning growth in the number of tests has been accompanied by increasing commercialization as well. The monthly *Monitor* published by the APA is replete with ads for test instruments for a wide spectrum of purposes. Likewise, APA conference attendees are inundated with preconference mailings advertising tests and detailing the location of the test publisher's booth at the conference site. Once at the conference, attendees are often struck by the slick presentation of the booths and hawking of the tests. Catalogs put out by test publishers are now also slick, in more ways than one. They are printed in color on coated paper and include a lot of messages about how convenient and useful the tests are with almost no information at all about reliability and validity beyond assurances that one can count on them.

The proliferation of assessment instruments and commercial development are not inherently detrimental to the field of clinical psychology. They simply make it more difficult to choose an appropriate test that is psychometrically sound, as glib ads can be used as a substitute for the presentation of sound psychometric properties and critical reviews. This is further complicated by the availability of computer scoring and software that can generate assessment reports. The ease of computer-based applications such as these can lead to their uncritical application by clinicians. Intense marketing of tests may contribute to their misuse, for example, by persuading clinical psychologists that the tests are remarkably simple and by convincing those same psychologists that they know more than they actually do about tests and their appropriate uses.

Multiple tests, even several tests for every construct, might not necessarily be a bad idea in and of itself, but we believe that the resources in psychology are simply not sufficient to support the proper development of so many tests. Few of the many tests available can possibly be used on more than a very few thousand cases per year, and perhaps not even that. The consequence is that profit margins are not sufficient to support really adequate test development programs. Tests are put on the market and remain there with small normative samples, with limited evidence for validity, which is much more expensive to produce than evidence for reliability, and with almost no prospect for systematic exploration of the other psychometric properties of the items, for example, discrimination functions or tests of their calibration (Sechrest, McKnight, & McKnight, 1996).

One of us (L. S.) happens to have been a close spectator of the development of the SF-36, a now firmly established and highly valued measure of health and functional status (Ware & Sherbourne, 1992). The SF-36 took 15–20 years for its development, having begun as an item pool of more than 300 items. Over the years literally millions of dollars were invested in the development of the test, and it was subjected, often repeatedly, to the most sophisticated psychometric analyses and to detailed scrutiny of every individual item. The SF-36 has now been translated into at least 37 languages and is being used in an extraordinarily wide variety of research projects. More important, however, the SF-36 is also being employed routinely in evaluating outcomes of clinical medical care. Plans are well advanced for use of the SF-36 that will result in its administration to 300 000 patients in managed care every year. It is possible that over the years the Wechsler intelligence tests might have a comparable history of development, and the Minnesota Multiphasic Inventory (MMPI) has been the focus of a great many investigations, as has the Rorschach. Neither of the latter, however, has been the object of systematic development efforts funded centrally, and scarcely any of the many other tests now available are likely to be subjected to anything like the same level of development effort (e.g., consider that in its more than 70-year history, the Rorschach has never been subjected to any sort of revision of its original items).

Several factors undoubtedly contribute to the proliferation of psychological tests (not the least, we suspect, being their eponymous designation and the resultant claim to fame), but surely one of the most important would be the fragmentation of psychological theory, or what passes for theory. In 1995 a taskforce was assembled under the auspices of the APA to try to devise a uniform test (core) battery that would be used in all psychotherapy research studies (Strupp, Horowitz, & Lambert, 1997). The effort failed, in large part because of the many points of view that seemingly had to be represented and the inability of the conferees to agree even on any outcomes that should be common to all therapies. Again, the contrast with medicine and the nearly uniform acceptance of the SF-36 is stark.

Another reason for the proliferation of tests in psychology is, unquestionably, the seeming ease with which they may be "constructed." Almost anyone with a reasonable "construct" can write eight or 10 self-report items to "measure" it, and most likely the new little scale will have "acceptable" reliability. A correlation or two with some other measure will establish its "construct validity," and the rest will eventually be history. All that is required to establish a new projective test, it seems, is to find a set of stimuli that have not, according to the published literature, been used before and then show that responses to the stimuli are suitably strange, perhaps stranger for some folks than others. For example, Sharkey and Ritzler (1985) noted a new Picture Projective Test that was created by using photographs from a photo essay. The pictures were apparently selected based on the authors' opinions about their ability to elicit "meaningful projective material," meaning responses with affective content and activity themes. No information was given pertaining to comparison of various pictures and their responses nor relationships to other measures of the target constructs; no comparisons were made to pictures that were deemed inappropriate. The "validation" procedure simply compared diagnoses to those in charts and results of the TAT. Although rater agreement was assessed, there was no formal measurement of reliability.

New tests are cheap, it seems. One concern is that so many new tests appear also to imply new constructs, and one wonders whether clinical psychology can support anywhere near as many constructs as are implied by the existence of so many measures of them. Craik (1986) made the eminently sensible suggestion that every "new" or infrequently used measure used in a research project should be accompanied by at least one well-known and widely used measure from the same or a closely related domain. New measures should be admitted only if it is clear that they measure something of interest and are not redundant, that is, have discriminant validity. That recommendation would likely have the effect of reducing the array of measures in clinical psychology by remarkable degrees if it were followed.

The number of tests that are taught in graduate school for clinical psychology is far lower than the number available for use. The standard stock-in-trade are IQ tests such as the Wechsler Adult Intelligence Scale (WAIS), personality profiles such as the MMPI, diagnostic instruments (Structured Clinical Interview for *DSM-III-R* [SCID]), and at some schools, the Rorschach as a projective test. This list is rounded out by a smattering of other tests like the Beck Depression Inventory and Millon. Recent standard application forms for clinical internships developed by the Association of Psychology Postdoctoral and Internship Centers (APPIC) asked applicants to report on their experience with 47 different tests and procedures used for adult assessment and 78 additional tests used with children! It is very doubtful that training programs actually provide training in more than a handful of the possible devices.

Training in testing (assessment) is not at all the same as training in measurement and psychometrics. Understanding how to administer a test is useful but cannot substitute for evaluating the psychometric soundness of tests. Without grounding in such principles, it is easy to fall prey to glib ads and ease of computer administration without questioning the quality of the test. Psychology programs appear, unfortunately, to be abandoning training in basic measurement and its theory (Aiken, West, Sechrest, & Reno, 1990).

4.01.2.4 Over-reliance on Self-report

"Where does it hurt?" is a question often heard in physicians' offices. The physician is asking the patient to self-report on the subjective experience of pain. Depending on the answer, the physician may prescribe some remedy, or may order tests to examine the pain more thoroughly and obtain objective evidence about the nature of the affliction before pursuing a course of treatment. The analog heard in psychologists' offices is "How do you feel?" Again, the inquiry calls forth self-report on a subjective experience and like the physician, the psychologist may determine that tests are in order to better understand what is happening with the client.

When the medical patient goes for testing, she or he is likely to be poked, prodded, or pricked so that blood samples and X-rays can be taken. The therapy client, in contrast, will most likely be responding to a series of questions in an interview or answering a pencil-and-paper questionnaire. The basic difference between these is that the client in clinical psychology will continue to use self-report in providing a sample, whereas the medical patient will provide objective evidence.

Despite the proliferation of tests in recent years, few rely on evidence other than the client's self-report for assessing behavior, symptoms, or mood state. Often assessment reports remark that the information gleaned from testing was corroborated by interview data, or vice versa, without recognizing that both rely on self-report alone. The problems with self-report are well documented: poor recall of past events, motivational differences in responding, social desirability bias, and malingering, for example. Over-reliance on self-report is a major criticism of psychological assessment as it is currently conducted and was the topic of a recent conference sponsored by the National Institute of Mental Health.

What alternatives are there to self-report? Methods of obtaining data on a client's behavior that do not rely on self-report do exist. Behavioral observation with rating by judges can permit the assessment of behavior, often without the client's awareness or outside the confines of an office setting. Use of other informants such as family members or co-workers to provide data can yield valuable information about a client. Yet, all too often these alternatives are not pursued because they involve time or resources—in short, they are demanding approaches. Compared with asking a client about his or her mood state over the last week, organizing field work or contacting informants involves a great deal more work and time.

Instruments are available to facilitate collection of data not relying so strongly on self-report and for collection of data outside the office setting, for example, the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983). The CBCL is meant to assist in diagnosing a range of psychological and behavior problems in children, and it relies on parent, teacher, and self-reports of behavior. Likewise, neuropsychological tests utilize functional performance measures much more than self-report. However, as Craik (1986) noted with respect to personality research, methods such as field studies are not widely used as alternatives to self-report. This problem of over-reliance on self-report is not new (see Webb, Campbell, Schwartz, & Sechrest, 1966).

4.01.3 PSYCHOMETRIC ISSUES WITH RESPECT TO CURRENT MEASURES

Consideration of the history and current status of clinical assessment must deal with some fundamental psychometric issues and practices. Although psychometric is usually taken to refer to reliability and validity of measures, matters are much more complicated than that, particularly in light of developments in psychometric theory and method since the 1960s, which seem scarcely to have penetrated clinical assessment as an area. Specifically, generalizability theory and Item Response Theory (IRT) offer powerful tools with which to explore and develop clinical assessment procedures, but they have seen scant use in that respect.

4.01.3.1 Reliability

The need for "reliable" measures is by now well accepted in all of psychology, including clinical assessment. What is not so widespread is the necessary understanding of what constitutes reliability and the various uses of that term. In their now classic presentation of generalizability theory, Cronbach and his associates (Cronbach, Gleser, Nanda, & Rajaratnam, 1972) used the term "dependability" in a way that is close to what is meant by reliability, but they made especially clear, as classical test theory had not, that measures are dependable (generalizable) in very specific ways, that is, that they are dependable across some particular conditions of use (facets), and assessments of dependability are not at all interchangeable. For example, a given assessment may be highly dependable across particular items but not necessarily across time. An example might be a measure of mood, which ought to have high internal consistency (i.e., across items) but that might not, in fact, should not, have high dependability over time, else the measure would be better seen as a trait rather than as a mood measure.

An assessment procedure might be highly dependable in terms of internal consistency and across time but not satisfactorily dependable across users, for example, being susceptible to a variety of biases characteristic of individual clinicians. Or an assessment procedure might not be adequately dependable across conditions of its use, as might be the case when a measure is taken from a research to a clinical setting. Or an assessment procedure might not be dependable across populations, for example, a projective instrument useful with mental patients might be misleading if used with imaginative and playful college students.

Issues of dependability are starkly critical when one notes the regrettably common practice of justifying the use of a measure on the ground that it is "reliable," often without even minimal specification of the facet(s) across which that reliability was established. The practice is even more regrettable when, as is often the case, only a single value for reliability is given when many are available and when one suspects that the figure reported was not chosen randomly from those available. Moreover, it is all too frequently the case that the reliability estimate reported is not directly relevant to the decisions to be made. Internal consistency, for example, may not be as important as generalizability over time when one is using a screening instrument. That is, if one is screening in a population for psychopathology, it may not be of great interest that two persons with the same scores are different in terms of their manifestations of pathology, but it is of great interest whether if one retested them a day or so later, the scores would be roughly consistent.

In short, clinical assessment in psychology is unfortunately casual in its use of reliability estimates, and it is shamefully behind the curve in its attention to the advantages provided by generalizability theory, originally proposed in 1963 (Cronbach, Rajaratnam, & Gleser, 1963).

4.01.3.2 Validity

It is customary to treat validity of measures as a topic separate from reliability, but we think that is not only unnecessary but undesirable. In our view, the validity of measures is simply an extension of generalizability theory to the question of what other performances aside from those involved in the test is the score generalizable. A test score that is generalizable to another very similar performance, say on the same set of test items or over a short period of time, is said to be reliable. A test score that is generalizable to a score on another similar test is sometimes said to be "valid," but we think that a little reflection will show that unless the tests demand very different kinds of performances, generalizability from one test to another is not much beyond the issues usually regarded as having to do with reliability. When, however, a test produces a score that is informative about another very different kind of performance, we gradually move over into the realm termed validity, such as when a paper-and-pencil test of "readiness for change" (Prochaska, DiClemente, & Norcross, 1992) predicts whether a client will benefit from treatment or even just stay in treatment.

We will say more later about construct validity, but a test or other assessment procedure may be said to have construct validity if it produces generalizable information and if that information relates to performances that are conceptually similar to those implied by the name or label given to the test. Essentially, however, any measure that does not produce scores by some random process is by that definition generalizable to some other performance and, hence, to that extent may be said to be valid. What a given measure is valid for, that is, generalizable to, however, is a matter of discovery as much as of plan. All instruments used in clinical assessment should be subjected to comprehensive and continuing investigation in order to determine the sources of variance in scores. An instrument that has good generalizability over time and across raters may turn out to be, among other things, a very good measure of some response style or other bias. The MMPI includes a number of "validity" scales designed to assess various biases in performance on it, and it has been subjected to many investigations of bias. The same cannot be said of some other widely used clinical assessment instruments and procedures. To take the most notable example, of the more than 1000 articles on the Rorschach that are in the current PsychInfo database, only a handful, about 1%, appear to deal with issues of response bias, and virtually all of those are on malingering and most of them are unpublished dissertations.

4.01.3.3 Item Response Theory

Although Item Response Theory (IRT) is a potentially powerful tool for the development and study of measures of many kinds, its use to date has not been extensive beyond the area of ability testing. The origins of IRT go back at least to the early 1950s and the publication of Lord's (1952) monograph, *A theory of test scores,* but it has had little impact on measurement outside the arena of ability testing (Meier, 1994). Certainly it has had almost no impact on clinical assessment. The current PsychInfo database includes only two references to IRT in relation to the MMPI and only one to the Rorschach, and the latter one, now 10 years old, is an entirely speculative mention of a potential application of IRT (Samejima, 1988).

IRT, perhaps to some extent narrowly imagined to be relevant only to test construction, can be of great value in exploring the nature of measures and improving their interpretation. For example, IRT can be useful in understanding just when scores may be interpreted as unidimensional and then in determining the size of gaps in underlying traits represented by adjacent scores. An example could be the interpretation of Whole responses on the Rorschach. Is the W score a unidimensional score, and, if so, is each increment in that score to be interpreted as an equal increment? Some cards are almost certainly more difficult stimuli to which to produce a W response, and IRT could calibrate that aspect of the cards. IRT would be even more easily used for standard paper-and-pencil inventory measures, but the total number of applications to date is small, and one can only conclude that clinical assessment is being short-changed in its development.

4.01.3.4 Scores on Tests

Lord's (1952) monograph was aimed at tests with identifiable underlying dimensions such as ability. Clinical assessment appears never to have had any theory of scores on instruments included under that rubric. That is, there seems never to have been proposed or adapted any unifying theory about how test scores on clinical instruments come about. Rather there seems to have been a passive, but not at all systematic, adoption of general test theory, that is, the idea that test scores are in some manner generated by responses representing some underlying trait. That casual approach cannot forward the development of the field.

Fiske (1971) has come about as close as anyone to formulating a theory of test scores for clinical assessment, although his ideas pertain more to how such tests are scored than to how they come about, and his presentation was directed toward personality measurement rather than clinical assessment. He suggested several models for scoring test, or otherwise observed, responses. The simplest model is what we may call the cumulative frequency model, which simply increments the score by 1 for every observed response. This is the model that underlies many Rorschach indices. It assumes that every response is equivalent to every other one, and it ignores the total number of opportunities for observation. Thus, each Rorschach W response counts as 1 for that index, and the index is not adjusted to take account of the total number of responses. A second model is the relative frequency model, which forms an index by dividing the number of observed critical responses by some indicator of opportunities to form a rate of responding, for example, as would be accomplished by counting W responses and dividing by the total number of responses or by counting W responses only for the first response to each card. Most paper-and-pencil inventories are scored implicitly in that way, that is, they count the number of critical responses in relation to the total number possible.

A long story must be made short here, but Fiske describes other models, and still more are possible. One may weight responses according to the inverse of their frequency in a population on the grounds that common responses should count for less than rare responses. Or one may weight responses according to the judgments of experts. One can assign the average weight across a set of responses, a common practice, but one can also assign as the score the weight of the most extreme response, for example, as runners are often rated on the basis of their fastest time for any given distance. Pathology is often scored in that way, for example, a pathognomic response may outweigh many mundane, ordinary responses.

The point is that clinical assessment instruments and procedures only infrequently have any explicit basis in a theory of responses. For the most part, scores appear to be derived in some standard way without much thought having been given to the process. It is not clear how much improvement in measures might be achieved by more attention to the development of a theory of scores, but it surely could not hurt to do so.

4.01.3.5 Calibration of Measures

A critical limitation on the utility of psychological measures of any kind, but certainly in their clinical application, is the fact that the measures do not produce scores in any directly interpretable metric. We refer to this as the *calibration* problem (Sechrest, McKnight, & McKnight, 1996). The fact is that we have only a very general knowledge of how test scores may be related to any behavior of real interest. We may know in general that a score of 70, let us say, on an MMPI scale is "high," but we do not know very well what might be expected in the behavior of a person with such a score. We would know even less about what difference it might make if the score were reduced to 60 or increased to 80 except that in one case we might expect some diminution in problems and in the other some increase. In part the lack of calibration of measures in clinical psychology stems from lack of any specific interest and diligence in accomplishing the task. Clinical psychology has been satisfied with "loose calibration," and that stems in part, as we will assert later, from adoption of the uninformative model of significance testing as a standard for validation of measures.

4.01.4 WHY HAVE WE MADE SO LITTLE PROGRESS?

It is difficult to be persuaded that progress in assessment in clinical psychology has been substantial in the past 75 years, that is, since the introduction of the Rorschach. Several arguments may be adduced in support of that statement, even though we recognize that it will be met with protests. We will summarize what we think are telling arguments in terms of theory, formats, and validities of tests.

First, we do not discern any particular improvements in theories of clinical testing and assessments over the past 75 years. The Rorschach, and the subsequent formulation of the projective hypothesis, may be regarded as having been to some extent innovations; they are virtually the last ones in the modern history of assessment. As noted, clinical assessment lags well behind the field in terms of any theory of either the stimuli or responses with which it deals, let alone the connections between them. No theory of assessment exists that would guide selection of stimuli to be presented to subjects, and certainly none pertains to the specific format of the stimuli nor to the nature of the responses required. Just to point to two simple examples of the deficiency in understanding of response options, we note that there is no theory to suggest whether in the case of a projective test responses should be followed by any sort of inquiry about their origins, and there is no theory to suggest in the case of self-report inventories whether items should be formulated so as to produce endorsements of the "this is true of me" nature or so as to produce descriptions such as "this is what I do."

Given the lack of any gains in theory about the assessment enterprise, it is not surprising that there have also not been any changes in test formats since the introduction of the Rorschach.

Projective tests based on the same simple (and inadequate) hypothesis are still being devised, but not one has proven itself in any way better than anything that has come before. Item writers may be a bit more sophisticated than those in the days of the Bernreuter, but items are still constructed in the same way, and response formats are the same as ever, "agree–disagree," "true–false," and so on.

Even worse, however, is the fact that absolutely no evidence exists to suggest that there have been any mean gains in the validities of tests over the past 75 years. Even for tests of intellectual functioning, typical correlations with any external criterion appear to average around 0.40, and for clinical and personality tests the typical correlations are still in the range of 0.30, the so-called "personality coefficient." This latter point, that validities have remained constant, may, of course, be related to the lack of development of theory and to the fact that the same test formats are still in place.

Perhaps some psychologists may take exception to the foregoing and cite considerable advances. Such claims are made for the Exner (1986) improvements on the Rorschach, known as the "comprehensive system," and for the MMPI-2, but although both claims are superficially true, there is absolutely no evidence for either claim from the standpoint of validity of either test. The Exner comprehensive system seems to have "cleaned up" some aspects of Rorschach scoring, but the improvements are marginal, for example, it is not as if inter-rater reliability increased from 0.0 to 0.8, and no improvements in validity have been established. Even the improvements in scoring have been demonstrated for only a portion of the many indexes. The MMPI-2 was only a cosmetic improvement over the original, for example, getting rid of some politically incorrect items, and no increase in the validity of any score or index seems to have been demonstrated, nor is any likely.

An additional element in the lack of evident "progress" in the validity of test scores may be lack of reliability (and validity!) of people being predicted. (One wise observer suggested that we would not really like it at all if behavior were 90% predictable! Especially our own.) We may just have reached the limits of our ability to predict what is going to happen with and to people, especially with our simple-minded and limited assessment efforts. As long as we limit our assessment efforts to the dispositions of the individuals who are clients and ignore their social milieus, their real environmental circumstances, their genetic possibilities, and so on, we may not be able to get beyond correlations of 0.3 or 0.4.

The main "advance" in assessment over the past 75 years is not that we do anything really better but that we do it much more widely. We have many more scales than existed in the past, and we can at least assess more things than ever before, even if we can do that assessment only, at best, passably well.

Woodworth (1937/1992) wrote in his article on the future of clinical psychology that, "There can be no doubt that it will advance, and in its advance throw into the discard much guesswork and half-knowledge that now finds baleful application in the treatment of children, adolescents and adults" (p. 16). It appears to us that the opposite has occurred. Not only have we failed to discard guesswork and half-knowledge, that is, tests and treatments with years of research indicating little effect or utility, we have continued to generate procedures based on the same flawed assumptions with the misguided notion that if we just make a bit of a change here and there, we will finally get it right. Projective assessments that tell us, for example, that a patient is psychotic are of little value. Psychologists have more reliable and less expensive ways of determining this. More direct methods have higher validity in the majority of cases. The widespread use of these procedures at high actual and opportunity cost is not justified by the occasional addition of information. It is not possible to know ahead of time which individuals might give more information via an indirect method, and most of the time it is not even possible to know afterwards whether indirectly obtained "information" is correct unless the information has also been obtained in some other way, that is, asking the person, asking a relative, or doing a structured interview. It is unlikely that projective test responses will alter clinical intervention in most cases, nor should it.

Is it fair to say that clinical psychology has no standards (see Sechrest, 1992)? Clinical psychology gives the appearance of standards with accreditation of programs, internships, licensure, ethical standards, and so forth. It is our observation, however, that there is little to no monitoring of the purported standards. For example, in reviewing recent literature as background to this chapter, we found articles published in peer-reviewed journals using projective tests as outcome measures for treatment. The APA ethical code of conduct states that psychologists "... use psychological assessment ... for purposes that are appropriate in light of the research on or evidence of the... proper application of the techniques." The APA document, *Standards for educational and psychological testing*, states:

> ... Validity however, is a unitary concept. Although evidence may be accumulated in may ways, validity always refers to the degree to which that evidence supports the inferences that are made from the scores. The inferences regarding specific uses of a test are validated, not the test itself. (APA, 1985, p. 9)

Further, the section titled, *Professional standards for test use* (APA, 1985, p. 42, Standard 6.3) states:

> When a test is to be used for a purpose for which it has not been previously validated, or for which there is no supported claim for validity, the user is responsible for providing evidence of validity.

No body of research exists to support the validity of any projective instrument as the sole outcome measure for treatment—or as the sole measure of anything. So not only do questionable practices go unchecked, they can result in publication.

4.01.4.1 The Absence of the Autopsy

Medicine has always been disciplined by the regular occurrence of the autopsy. A physician makes a diagnosis and treats a patient, and if the patient dies, an autopsy will be done, and the physician will receive feedback on the correctness of his or her diagnosis. If the diagnosis were wrong, the physician would to some extent be called to account for that error; at least the error would be known, and the physician could not simply shrug it off. We know that the foregoing is idealized, that autopsies are not done in more than a fraction of cases, but the model makes our point. Physicians make predictions, and they get feedback, often quickly, on the correctness of those predictions. Surgeons send tissue to be biopsied by pathologists who are disinterested; internists make diagnoses based on various signs and symptoms and then order laboratory procedures that will inform them about the correctness of their diagnosis; family practitioners make diagnoses and prescribe treatment, which, if it does not work, they are virtually certain to hear about.

Clinical psychology has no counterpart to the autopsy, no systematic provision for checking on the correctness of a conclusion and then providing feedback to the clinician. Without some form of systematic checking and feedback, it is difficult to see how improvement in either instruments or clinicians' use of them could be regularly and incrementally improved. Psychologist clinicians have been allowed the slack involved in making unbounded predictions and then not getting any sort of feedback on the potential accuracy of even those loose predictions. We are not sure how much improvement in clinical assessment might be possible even with exact and fairly immediate feedback, but we are reasonably sure that very little improvement can occur without it.

4.01.5 FATEFUL EVENTS CONTRIBUTING TO THE HISTORY OF CLINICAL ASSESSMENT

The history of assessment in clinical psychology is somewhat like the story of the evolution of an organism in that at critical junctures, when the development of assessment might well have gone one way, it went another. We want to review here several points that we consider to be critical in the way clinical assessment developed within the broader field of psychology.

4.01.5.1 The Invention of the Significance Test

The advent of hypothesis testing in psychology had fateful consequences for the development of clinical assessment, as well as for the rest of psychology (Gigerenzer, 1993). Hypothesis testing encouraged a focus on the question whether any predictions or other consequences of assessment were "better than chance," a distinctly loose and undemanding criterion of "validity" of assessment. The typical validity study for a clinical instrument would identify two groups that would be expected to differ in some "score" derived from the instrument and then ask the question whether the two groups did in fact (i.e., to a statistically significant degree) differ in that score. It scarcely mattered by how much they differed or in what specific way, for example, an overall mean difference vs. a difference in proportions of individuals scoring beyond some extreme or otherwise critical value. The existence of any "significant" difference was enough to justify triumphant claims of validity.

4.01.5.2 Ignoring Decision Making

One juncture had to do with bifurcation of the development of clinical psychology from other streams of assessment development. Specifically, intellectual assessment and assessment of various capacities and propensities relevant to performance in work settings veered in the direction of assessment for decision-making (although not terribly sharply nor completely), while assessment in clinical psychology went in the direction of assessment for enlightenment. What eventually happened is that clinical psychology failed to adopt any rigorous criterion of correctness of decisions made on the basis of assessed performance, but adopted instead a conception of assessments as generally informative or "correct."

Simply to make the alternative clear, the examples provided by medical assessment are instructive. The model followed in psychology would have resulted in medical research of some such nature as showing that two groups that "should" have differed in blood pressure, for example, persons having just engaged in vigorous exercise vs. persons having just experienced a rest period, differed significantly in blood pressure readings obtained by a sphygmomanometer. Never mind by how much they differed or what the overlap between the groups. The very existence of a "significant" difference would have been taken as evidence for the "validity" of the sphygmomanometer.

Instead, however, medicine focused more sharply on the accuracy of decisions made on the basis of assessment procedures. The aspect of biomedical assessment that most clearly distinguishes it from clinical psychological assessment is its concern for sensitivity and specificity of measures (instruments) (Kraemer, 1992). Kraemer's book, *Evaluating medical tests: Objective and quantitative guidelines,* has not even a close counterpart in psychology, which is, itself, revealing. These two characteristics of measures are radically different from the concepts of validity used in psychology, although "criterion validity" (now largely abandoned) would seem to require such concepts.

Sensitivity refers to the proportion of cases having a critical characteristic that are identified by the test. For example, if a test were devised to select persons likely to benefit from some form of therapy, sensitivity would refer to the proportion of cases that would actually benefit which would be identified correctly by the test. These cases would be referred to as "true positives." Any cases that would benefit from the treatment but that could not be identified by the test would be "false-negatives" in this example. Conversely, a good test should have high specificity, which would be avoiding "false-positives," or incorrectly identifying as good candidates for therapy persons who would not actually benefit. The "true negative" group would be those persons who would not benefit from treatment, and a good test should correctly identify a large proportion of them.

As Kraemer (1992) points out, sensitivity and specificity as test requirements are nearly always in opposition to each other, and are reciprocal. Maximizing one requirement reduces the other. Perfect sensitivity can be attained by, in our example, a test that identifies every case as suitable for therapy; no amenable cases are missed. Unfortunately, that maneuver would also maximize the number of false-positives, that is, many cases would be identified as suitable for therapy who, in fact, were not. Obviously, the specificity of the test could be maximized by declaring all cases as unsuitable for therapy, thus ensuring that the number of false-positives would be zero—while at the same time ensuring that the number of false-negatives would be maximal, and no one would be treated.

We go into these issues in some detail in order to make clear how very different such thinking is from usual practices in clinical psychological assessment. The requirements for Receiver Operating Curves (ROC), which is the way issues of sensitivity and specificity of measures are often labeled and portrayed, are stringent. They are not satisfied by simple demonstrations that measures, for example, suitability for treatment, are "significantly related to" other measures of interest, for example, response to treatment. The development of ROC statistics almost always occurs in the context of the use of tests for decision-making: treat–not treat, hire–not hire, do further tests–no further tests. Those kinds of uses of tests in clinical psychological assessment appear to be rare.

Issues of sensitivity-specificity require the existence of some reasonably well-defined criterion, for example, the definition of what is meant by favorable response to treatment and a way of measuring it. In biomedical research, ROC statistics are often developed in the context of a "gold standard," a definitive criterion. For example, an X ray might serve as a gold standard for a clinical judgment about the existence of a fracture, or a pathologist's report on a cytological analysis might serve as a gold standard for a screening test designed to detect cancer. Clinical psychology has never had anything like a gold standard against which its various tests might have been validated. Psychiatric diagnosis has sometimes been of interest as a criterion, and tests of different types have been examined to determine the extent to which they produce a conclusion in agreement with diagnosis (e.g., Somoza, Steer, Beck, & Clark, 1994), but in that case the gold standard is suspect, and it is by no means clear that disagreement means that the test is wrong.

The result is that for virtually no psychological instrument is it possible to produce a useful quantitative estimate of its accuracy. Tests and other assessment devices in clinical psychology have been used for the most part to produce general enlightenment about a target of interest rather than to make a specific prediction of some outcome. People who have been tested are described as "high in anxiety," "clinically depressed," or "of average intelligence." Statements of that sort, which we have referred to previously as unbounded predictions, are possibly enlightening about the nature of a person's functioning or about the general range within which problems fall, but they are not specific predictions, and are difficult to refute.

4.01.5.3 Seizing on Construct Validity

In 1955, Cronbach and Meehl published what is arguably the most influential article in the field of measurement: *Construct validity in psychological tests* (Cronbach & Meehl, 1955). This is the same year as the publication of *Antecedent probability and the efficiency of psychometric signs, patterns, or cutting scores* (Meehl & Rosen, 1955). It is safe to say that no two more important articles about measurement were ever published in the same year. The propositions set forth by Cronbach and Meehl about the validity of tests were provocative and rich with implications and opportunities. In particular, the idea of construct validity required that measures be incorporated into elaborated theoretical structure, which was labeled the "nomological net." Unfortunately, the fairly daunting requirements for embedding measures in theory were mostly ignored in clinical assessment (the same could probably be said about most other areas of psychology, but it is not our place here to say so), and the idea of construct validity was trivialized.

The trivialization of construct validity reflects in part the fact that no standards for construct validity exist (and probably none can be written) and the general failure to distinguish between necessary and sufficient conditions for the inference of construct validity. In their presentation of construct validity, Cronbach and Meehl did not specify any particular criteria for sufficiency of evidence, and it would be difficult to do so. Construct validity exists when everything fits together, but trying to specify the number and nature of the specific pieces of evidence would be difficult and, perhaps, antithetical to the idea itself. It is also not possible to quantify level or degree of construct validity other than in a very rough way and such quantifications are, in our experience, rare. It is difficult to think of an instance of a measure described as having "moderate or "low" construct validity, although "high" construct validity is often implied.

It is possible to imagine what some of the necessary conditions for construct validity might be, one notable requirement being convergent validity (Campbell & Fiske, 1959). In some manner that we have not tried to trace, conditions necessary for construct validity came to be viewed as sufficient. Thus, for example, construct validity usually requires that one measure of a construct correlates with another. Such a correlation is not, however, a sufficient condition for construct validity, but, nonetheless, a simple zero-order correlation between two tests is often cited as "evidence" for the construct validity of one measure or the other. Even worse, under the pernicious influence of the significance testing paradigm, any statistically significant correlation may be taken as evidence of "good construct validity." Or, for another example, construct validity usually requires a particular factor structure for a measure, but the verification of the required factor structure is not sufficient evidence for construct validity of the measure involved. The fact that a construct is conceived as unidimensional does not mean that a measure alleged to represent the construct does so simply because it appears to form a single factor.

The net result of the dependence on significance testing and the poor implementation of the ideas represented by construct validity has been that the standards of evidence for the validity of psychological measures has been distressingly low.

4.01.5.4 Adoption of the Projective Hypothesis

The projective hypothesis (Frank, 1939) is a general proposition stating that whatever an individual does when exposed to an ambiguous stimulus will reveal important aspects of his or her personality. Further, the projective hypothesis suggests that indirect responses, that is, those to ambiguous stimuli, are more valid than direct responses, that is, those to interviews or questionnaires. There is little doubt that indirect responses reveal something about people, although whether that which is revealed is, in fact, important is more doubtful. Moreover, what one eats, wears, listens to, reads, and so on are rightly considered to reveal something about that individual. While the general proposition about responses to ambiguous stimuli appears quite reasonable, the use of such stimuli in the form of projective tests has proven problematic and of limited utility.

The course of development of clinical assessment might have been different and more useful had it been realized that projection was the wrong term for the link between ambiguous stimuli and personality. A better term would have been the "expressive hypothesis," the notion that an individual's personality may be manifest (expressed) in response to a wide range of stimuli, including ambiguous stimuli. Personality style might have come to be of greater concern, and unconscious determinants of behavior, implied by projection, might have received less emphasis.

In any case, when clinical psychology adopted the projective hypothesis and bought wholesale into the idea of unconscious determinants of behavior, that set the field on a course that has been minimally productive but that still affects an extraordinarily wide range of clinical activities. Observable behaviors have been downplayed and objective measures treated with disdain or dismissed altogether. The idea of peering into the unconscious appealed both to psychological voyeurs and to those bent on achieving the glamour attributed to the psychoanalyst.

Research on projective stimuli indicates that highly structured stimuli which limit the dispositions tapped increase the reliability of such tests (e.g., Kagan, 1959). In achieving acceptable reliability, the nature of the test is altered in such a way that the stimulus is less ambiguous and the likelihood of an individual "projecting" some aspect of their personality in an unusual way becomes reduced. Thus, the dependability of responses to projective techniques probably depends to an important degree on sacrificing their projective nature. In part, projective tests seem to have failed to add to assessment information because most of the variance in responses to projective stimuli is accounted for by the stimuli themselves. For example, "popular" responses on the Rorschach are popular because the stimulus is the strongest determinant of the response (Murstein, 1963).

Thorndike (Thorndike & Hagen, 1955, p. 418), in describing the state of affairs with projective tests some 40 years ago, stated:

> A great many of the procedures have received very little by way of rigorous and critical test and are supported only by the faith and enthusiasm of their backers. In those few cases, most notable that of the Rorschach, where a good deal of critical work has been done, results are varied and there is much inconsistency in the research picture. Modest reliability is usually found, but consistent evidence of validity is harder to come by.

The picture has not changed substantially in the ensuing 40 years and we doubt that it is likely to change much in the next 40. As Adcock (1965, cited in Anastasi, 1988) noted, "There are still enthusiastic clinicians and doubting statisticians." As noted previously (Sechrest, 1963, 1968), these expensive and time-consuming projective procedures add little if anything to the information gained by other methods and their abandonment by clinical psychology would not be a great loss. Despite lack of incremental validity after decades of research, not only do tests such as the Rorschach and TAT continue to be used, but new projective tests continue to be developed. That could be considered a pseudoscientific enterprise that, at best, yields procedures telling clinical psychologists what they at least should already know or have obtained in some other manner, and that, at worst, wastes time and money and further damages the credibility of clinical psychology.

4.01.5.5 The Invention of the Objective Test

At one time we had rather supposed without thinking about it too much that objective tests had always been around in some form or other. Samelson (1987), however, has shown that at least the multiple-choice test was invented in the early part of the twentieth century, and it seems likely that the true–false test had been devised not too long before then. The objective test revolutionized education in ways that Samelson makes clear, and it was not long before that form of testing infiltrated into psychology. Bernreuter (1933) is given credit for devising the first multiphasic (multidimensional) personality inventory—only 10 years after the introduction of the Rorschach into psychology.

Since 1933, objective tests have flourished. In fact, they are now much more widely used than projective tests and are addressed toward almost every imaginable problem and aspect of human behavior. The Minnesota Multiphasic Personality Inventory (1945) was the truly landmark event in the course of development of paper-and-pencil instruments for assessing clinical aspects of psychological functioning. "Paper-and-pencil" is often used synonymously with "objective" in relation to personality. From that time on, other measures flourished, of recent in great profusion.

Paper-and-pencil tests freed clinicians from the drudgery of test administration, and in that way they also made testing relatively inexpensive as a clinical enterprise. They also made tests readily available to psychologists not specifically trained on them, including psychologists at subdoctoral levels. Paper-and-pencil measures also seemed so easy to administer, score, and interpret. As we have noted previously, the ease of creation of new measures had very substantial effects on the field, including clinical assessment.

4.01.5.6 Disinterest in Basic Psychological Processes

Somewhere along the way in its development, clinical assessment became detached from the mainstream of psychology and, therefore, from the many developments in basic psychological theory and knowledge. The Rorschach was conceived not as a test of personality *per se* but in part as an instrument for studying perception and Rorschach referred to it as his "experiment" (Hunt, 1956). Unfortunately, the connections of the Rorschach to perception and related mental processes were lost, and clinical psychology became preoccupied not with explaining how Rorschach responses come to be made but in explaining how Rorschach responses reflect back on a narrow range of potential determinants: the personality characteristics of respondents, and primarily their pathological characteristics at that.

It is testimony to the stasis of clinical assessment that three-quarters of a century after the introduction of the Rorschach, a period of time marked by stunning (relatively) advances in understanding of such basic psychological processes as perception, cognition, learning, and motivation and by equivalent or even greater advances in understanding of the biological structures and processes that underlie human behavior, the Rorschach continues, virtually unchanged, to be the favorite instrument for clinical assessment. The Exner System, although a revision of the scoring system, in no way reflects any basic changes in our advancement of understanding of the psychological knowledge base in which the Rorschach is, or should be, embedded. Take, just for one instance, the great increase of interest in and understanding of "priming" effects in cognition; those effects would clearly be relevant to the understanding of Rorschach responses, but there is no indication at all of any awareness on the part of those who write about the Rorschach that any such effect even exists. It was known a good many years ago that Rorschach responses could be affected by the context of their administration (Sechrest, 1968), but without any notable effect on their use in assessment.

Nor do any other psychological instruments show any particular evidence of any relationship to the rest of the field of psychology. Clinical assessment could have benefited greatly from a close and sensitive connection to basic research in psychology. Such a connection might have fostered interest in clinical assessment in the development of instruments for the assessment of basic psychological processes.

Clinical psychology has—is afflicted with, we might say—an extraordinary number of different tests, instruments, procedures, and so on. It is instructive to consider the nature of all these tests; they are quite diverse. (We use the term "test" in a somewhat generic way to refer to the wide range of mechanisms by which psychologists carry out assessments.) Whether the great diversity is a curse or a blessing depends on one's point of view. We think that a useful perspective is provided by contrasting psychological measures with those typically used in medicine, although, obviously, a great many differences exist between the two enterprises. Succinctly, however, we can say that most medical tests are very narrow in their intent, and they are devised to tap basic states or processes. A screening test for tuberculosis, for example, involves subcutaneous injection of tuberculin which, in an infected person, causes an inflammation at the point of injection. The occurrence of the inflammation then leads to further narrowly focused tests. The inflammation is not tuberculosis but a sign of its potential existence. A creatinine clearance test is a test of renal function based on the rate of clearance of ingested creatinine from the blood. A creatinine clearance test can indicate abnormal renal functioning, but it is a measure of a fundamental physiological process, not a state, a problem, a disease, or anything of that sort. A physician who is faced with the task of diagnosing some disease process involving renal malfunction will use a variety of tests, not necessarily specified by a protocol (battery) to build an information base that will ultimately lead to a diagnosis.

By contrast, psychological assessment is, by and large, not based on measurement of basic psychological processes, with few exceptions. Memory is one function that is of interest to neuropsychologists, and occasionally to others, and instruments to measure memory functions do exist. Memory can be measured independently of any other functions and without regard to any specific causes of deficiencies. Reaction time is another basic psychological process. It is currently used by cognitive psychologists as a proxy for mental processing time, and since the 1970s, interest in reaction time as a marker for intelligence has grown and become an active research area.

For the most part, however, clinical assessment has not been based on tests of basic psychological functions, although the Wechsler intelligence scales might be regarded as an exception to that assertion. A very large number of psychological instruments and procedures are aimed at assessing syndromes or diagnostic conditions, whole complexes of problems. Scales for assessing attention deficit disorder (ADD), suicide probability, or premenstrual syndrome (PMS) are instances. Those instruments are the equivalent of a medical "Test for Diabetes," which does not exist. The Conners' Rating Scales (teachers) for ADD, for example, has subscales for Conduct Problem, Hyperactivity, Emotional Overindulgent, Asocial, Anxious-Passive, and Daydream-Attendance. Several of the very same problems might well be represented on other instruments for entirely different disorders. But if they were, they would involve a different set of items, perhaps with a slightly different twist, to be integrated in a different way. Psychology has no standard ways of assessing even such fundamental dispositions as "asocial."

One advantage of the medical way of doing things is that tests like creatinine clearance have been used on millions of persons, are highly standardized, have extremely well-established norms, and so on. Another set of ADD scales, the Brown, assesses "ability to activate and organize work tasks." That sounds like an important characteristic of children, so important that one might think it would be widely used and useful. Probably, however, it appears only on the Brown ADD Scales, and it is probably little understood otherwise.

Clinical assessment has also not had the benefit of careful study from the standpoint of basic psychological processes that affect the clinician and his or her use and interpretation of psychological tests. Achenbach (1985), to cite a useful perspective, discusses clinical assessment in relation to the common sources of error in human judgment. Achenbach refers to such problems as illusory correlation, inability to assess covariation, and the representativeness and availability heuristics and confirmatory bias described by Kahneman, Slovic, and Tversky (1982). Consideration of these sources of *human*, that is, general, error in judgment would be more likely if clinical assessment were more attuned to and integrated into the mainstream developments of psychology.

We do not suppose that clinical assessment should be limited to basic psychological processes; there may well be a need for syndrome-oriented or condition-oriented instruments. Without any doubt, however, clinical assessment would be on a much firmer footing if from the beginning psychologists had tried to define and measure well a set of fundamental psychological processes that could be tapped by clinicians faced with diagnostic or planning problems.

Unfortunately, measurement has never been taken seriously in psychology, and it is still lightly regarded. One powerful indicator of the casual way in which measurement problems are met in clinical assessment is the emphasis placed on brevity of measures. "... entire exam can be completed... in just 20 to 30 minutes" (for head injury), "completed in just 15–20 minutes" (childhood depression), "39 items" (to measure six factors involved in ADD) are just a few of the notations concerning tests that are brought to the attention of clinician-assessors by advertisers. It would be astonishing to think of a medical test advertised as "diagnoses brain tumors in only 15 minutes," or "complete diabetes workup in only 30 minutes." An MRI examination for a patient may take up to several hours from start to finish, and no one suggests a "short form" of one. Is it imaginable that one could get more than the crudest notion of childhood depression in 15–20 minutes?

4.01.6 MISSED SIGNALS

At various times in the development of clinical psychology, opportunities existed to guide, or even redirect, assessment activities in one way or another. Clinical psychology might very well have taken quite a different direction than it has (Sechrest, 1992). Unfortunately, in our view, a substantial number of critical "signals to the field were missed, and entailed in missing them was failure to redirect the field in what would have been highly constructive ways.

4.01.6.1 The Scientist–Practitioner Model

We do not have the space to go into the intricacies of the scientist–practitioner model of training and practice, but it appears to be an idea whose time has come and gone. Suffice it to say here that full adoption of the model would not have required every clinical practitioner to be a researcher, but it would have fostered the idea that to some extent every practitioner is responsible for the scientific integrity of his or her own practice, including the validity of assessment procedures. The scientist–practitioner model might have helped clinical psychologists to be involved in research, even if only as contributors rather than as independent investigators.

That involvement could have been of vital importance to the field. The development of psychological procedures will never be supported commercially to any appreciable extent, and if they are to be adequately developed, it will have to be with the voluntary—and enthusiastic—participation of large numbers of practitioners who will have to contribute data, be involved in the identification of problems, and so on. That participation would have been far more likely had clinical psychology stuck to its original views of itself (Sechrest, 1992).

4.01.6.2 Construct Validity

We have already discussed construct validity at some length, and we have explained our view that the idea has been trivialized, in essence abandoned. That is another lost opportunity, because the power of the original formulation by Cronbach and Meehl (1955) was great. Had their work been better understood and honestly adopted, clinical psychology would by this time almost certainly have had a set of well-understood and dependable measures and procedures. The number and variety of such measures would have been far less than exists now, and the dependability of them would have been circumscribed, but surely it would have been better to have good than simply many measures.

4.01.6.3 Assumptions Underlying Assessment Procedures

In 1952, Lindzey published a systematic analysis of assumptions underlying the use of projective techniques (Lindzey, 1952). His paper was a remarkable achievement, or would have been had anyone paid any attention to it. The Lindzey paper could have served as a model and stimulus for further formulations leading to a theory, comprehensive and integrated, of performance on clinical instruments. A brief listing of several of the assumptions must suffice to illustrate what he was up to:

> IV. The particular response alternatives emitted are determined not only by characteristic response tendencies (enduring dispositions) but also by intervening defenses and his cognitive style.
>
> XI. The subject's characteristic response tendencies are sometimes reflected indirectly or symbolically in the response alternatives selected or created in the test situation.
>
> XIII. Those responses that are elicited or produced under a variety of different stimulus conditions are particularly likely to mirror important aspects of the subject.
>
> XV. Responses that deviate from those typically made by other subjects to this situation are more likely to reveal important characteristics of the subject than modal responses which are more like those made by most other subjects.

These and other assumptions listed by Lindzey could have provided a template for systematic development of both theory and programs of research aimed at supporting the empirical base for projective—and other—testing. Assumption XI, for example, would lead rather naturally to the development of explicit theory, buttressed by empirical data, which would indicate just when responses probably should and should not be interpreted as symbolic.

Unfortunately, Lindzey's paper appears to have been only infrequently cited and to have been substantially ignored by those who were engaged in turning out all those projective tests, inventories, scales, and so on. At this point we know virtually nothing more about the performance of persons on clinical instruments than was known by Lindzey in 1952. Perhaps even less.

4.01.6.4 Antecedent Probabilities

In 1955 Meehl and Rosen published an exceptional article on antecedent probabilities and the problem of base rates. The article was, perhaps, a bit mathematical for clinical psychology, but it was not really difficult to understand, and its implications were clear. Whenever one is trying to predict (or diagnose) a characteristic that is quite unevenly distributed in a population, the difficulty in beating the accuracy of the simple base rates is formidable, sometimes awesomely so. For example, even in a population considered at high risk for suicide, only a very few persons will actually commit suicide. Therefore, unless a predictive measure is extremely precise, the attempt to identify those persons who will commit suicide will identify as suicidal a relatively large number of "false-positives," that is, if one wishes to be sure not to miss any truly suicidal people, one will include in the "predicted suicide" group a substantial number of people not so destined. That problem is a serious to severe limitation when the cost of missing a true-positive is high, but so, relatively, is the cost of having to deal with a false-positive.

More attention to the difficulties described by Meehl and Rosen (1955) would have moved psychological assessment in the direction taken by medicine, that is, the use of ROCs. Although ROCs do not make the problem go away, they keep it in the forefront of attention and require that those involved, whether researchers or clinicians, deal with it. That signal was missed in clinical psychology, and it is scarcely mentioned in the field today. Many indications exist that a large proportion of clinical psychologists are quite unaware that the problem even exists, let alone that they have an understanding of it.

4.01.6.5 Need for Integration of Information

Many trends over the years converge on the conclusion that psychology will make substantial progress only to the extent that it is able to integrate its theories and knowledge base with those developing in other fields. We can address this issue only on the basis of personal experience; we can find no evidence for our view. Our belief is that clinical assessment in psychology rarely results in a report in which information related to a subject's genetic disposition, family structure, social environment, and so on are integrated in a systematic and effective way.

For example, we have seen many reports on patients evaluated for alcoholism without any attention, let alone systematic attention, to a potential genetic basis for their difficulty. At most a report might include a note to the effect that the patient has one or more relatives with similar problems. Never was any attempt made to construct a genealogy that would include other conditions likely to exist in the families of alcoholics. The same may be said for depressed patients. It might be objected that the responsibilities of the psychologist do not extend into such realms as genetics and family and social structure, but surely that is not true if the psychologist aspires to be more than a sheer technician, for example, serving the same function as a laboratory technician who provides a number for the creatinine clearance rate and leaves it to someone else, "the doctor," to put it all together.

That integration of psychological and other information is of great importance has been implicitly known for a very long time. That knowledge has simply never penetrated training programs and clinical practice. That missed opportunity is to the detriment of the field.

4.01.6.6 Method Variance

The explicit formulation of the concept of method variance was an important development in the history of assessment, but one whose import was missed or largely ignored. The concept is quite simple: to some extent, the value obtained for the measurement of any variable depends in part on the characteristics of the method used to obtain the estimate. (A key idea is the understanding that any specific value is, in fact, an estimate.) The first explicit formulation of the idea of method variance was the seminal Campbell and Fiske paper on the "multitrait-multimethod matrix" (Campbell & Fiske, 1959). (That paper also introduced the very important concepts of "convergent" and "discriminant" validity, now widely employed but, unfortunately, not always very well understood.) There had been precursors of the idea of method variance. In fact, much of the interest in projective techniques stemmed from the idea that they would reveal aspects of personality that would not be discernible from, for example, self-report measures. The MMPI, first published in 1943 (Hathaway & McKinley), included "validity" scales that were meant to detect, and, in the case of the K-scale, even correct for, methods effects such as lying, random responding, faking, and so on. By 1960 or so, Jackson and Messick had begun to publish their work on response styles in objective tests, including the MMPI (e.g., Jackson & Messick, 1962). At about the same time, Berg (1961) was describing the "deviant response tendency," which was the hypothesis that systematic variance in test scores could be attributed to general tendencies on the part of some respondents to respond in deviant ways. Nonetheless, it was the Campbell and Fiske (1959) paper that brought the idea of method variance to the attention of the field.

Unfortunately, the cautions expressed by Campbell and Fiske, as well as by others working on response styles and other method effects, appear to have had little effect on developments in clinical assessment. For the most part, the problems raised by methods effects and response styles appear to have been pretty much ignored in the literature on clinical assessment. A search of a current electronic database in psychology turned up, for example, only one article over the past 30 years or so linking the Rorschach to any discussion of method effects (Meyer, 1996). When one considers the hundreds of articles having to do with the Rorschach that were published during that period of time, the conclusion that method effects have not got through to the attention of the clinical assessment community is unavoidable. The consequence almost surely is that clinical assessments are not being corrected, at least not in any systematic way, for method effects and response biases.

4.01.6.7 Multiple Measures

At least a partial response to the problem of method effects in assessment is the use of multiple measures, particularly measures that do not appear to share sources of probable error or bias. That recommendation was explicit in Campbell and Fiske (1959), and it was echoed and elaborated upon in 1966 (Webb et al., 1966), and again in 1981 (Webb et al., 1981). Moreover, Webb and his colleagues warned specifically against the very heavy reliance on self-report measures in psychology (and other social sciences). That warning, too, appears to have made very little difference in practice. Examination of catalogs of instruments meant to be used in clinical assessment will show that a very large proportion of them depend upon self-reports of individual subjects about their own dispositions, and measures that do not rely directly on self-reports nonetheless do nearly all rely solely on the verbal responses of subjects. Aside from rating scales to be used with parents, teachers, or other observers of behavior, characteristics of interest such as personality and psychopathology almost never require anything of a subject other than a verbal report. By contrast, ability tests almost always require subjects to do something, solve a problem, complete a task, or whatever. Wallace (1966) suggested that it might be useful to think of traits as abilities, and following that lead might very well have expanded the views of those interested in furthering clinical assessment.

4.01.7 THE ORIGINS OF CLINICAL ASSESSMENT

The earliest interest in clinical assessment was probably that used for the classification of the "insane" and mentally retarded in the early 1800s. Because there was growing interest in understanding and implementing the humane treatment of these individuals, it was first necessary to distinguish between the two types of problems. Esquirol (1838), a French physician, published a two-volume document outlining a continuum of retardation based primarily upon language (Anastasi, 1988).

Assessment in one form or another has been part of clinical psychology from its beginnings. The establishment of Wundt's psychological laboratory at Leipzig in 1879 is considered by many to represent the birth of psychology. Wundt and the early experimental psychologists were interested in uniformity rather than assessment of the individual. In the Leipzig lab, experiments investigated psychological processes affected by perception, in which Wundt considered individual differences to be error. Accordingly, he believed that since sensitivity to stimuli differs, using a standard stimulus would compensate and thus eliminate individual differences (Wundt, Creighton, & Titchener, 1894/1896).

4.01.7.1 The Tradition of Assessment in Psychology

Sir Francis Galton's efforts in intelligence and heritability pioneered both the formal testing movement and field testing of ideas. Through his Anthropometric Laboratory at the International Exposition in 1884, and later at the South Kensington Museum in London, Galton gathered a large database on individual differences in vision, hearing, reaction time, other sensorimotor functions, and physical characteristics. It is interesting to note that Galton's proposition that sensory discrimination is indicative of intelligence continues to be promoted and investigated (e.g., Jensen, 1992). Galton also used questionnaire, rating scale, and free association techniques to gather data.

James McKeen Cattell, the first American student of Wundt, is credited with initiating the individual differences movement. Cattell, an important figure in American psychology, (Fourth president of the American Psychological Association and the first psychologist elected to the National Academy of Science) became interested in whether individual differences in reaction time might shed light on consciousness and, despite Wundt's opposition, completed his dissertation on the topic. He wondered if, for example, some individuals might be observed to have fast reaction time across situations and supposed that the differences may have been lost in the averaging techniques used by Wundt and other experimental psychologists (Wiggins, 1973). Cattell later became interested in the work of Galton and extended his work by applying reaction time and other physiological processes as measures of intelligence. Cattell is credited with the first published reference to a mental test in the psychological literature (Cattell, 1890).

Cattell remained influenced by Wundt in his emphasis on psychophysical processes. Although physiological functions could be easily and accurately measured, attempts to relate them to other criteria, however, such as teacher ratings of intelligence and grades, yielded poor results (Anastasi, 1988).

Alfred Binet conducted extensive and varied research on the measurement of intelligence. His many approaches included measurements of cranial, facial, and hand form, handwriting analysis, and inkblot tests. Binet is best known for his work in the development of intelligence scales for children. The earliest form of the scale, the Binet–Simon, was developed following Binet's appointment to a governmental commission to study the education of retarded children (Binet & Simon, 1905). The scale assessed a range of abilities with emphasis on comprehension, reasoning, and judgment. Sensorimotor and perceptual abilities were relatively less prominent, as Binet considered the broader process, for example, comprehension, to be central to intelligence. The Binet–Simon scale consisted of 30 problems arranged in order of difficulty. These problems were normed using 50 3–11-year-old normal children and a few retarded children and adults.

A second iteration, the 1908 scale, was developed. The 1908 scale was somewhat longer and normed on approximately 300 3–13-year-old normal children. Performance was grouped by age according to the level at which 80–90% of the normal children passed, giving rise to the term "mental age."

The Binet–Simon has been revised, translated, and adapted in numerous languages. Perhaps the most well-known revision was directed by Lewis Terman (1916) at Stanford University and this test is what is known as the Stanford–Binet. The Stanford–Binet was the origin of the intelligence quotient (IQ), the ratio between chronological and mental ages.

4.01.7.1.1 Witmer

Lightner Witmer, who studied with both Cattell and Wundt, established the first American psychological clinic at the University of Pennsylvania in 1896. This event is considered by many as the beginning of clinical psychology (Garfield, 1965; McReynolds, 1987, 1996). Witmer's approach to assessment was focused on determining the causes of children's problems and then to make recommendations for treatment. Diagnoses, *per se*, were not considered important, however, Witmer did make use of the Stanford–Binet and other formal assessment tools. McReynolds (1996) noted that Witmer strongly emphasized both direct observation and extensive background data as especially important for assessment.

Although Witmer characterized his work as practical, he remained committed to a scientific basis for psychology (McReynolds, 1996). It seems reasonable to conclude that Witmer was interested in assessment for bounded inference and prediction. That is, he wanted information as it might relate to specific problems for the express purpose of treating those problems (Witmer, 1996/1907).

4.01.7.1.2 Army Alpha

Robert M. Yerkes initiated and administered a program to test 1.75 million army recruits during World War I. This program, which Yerkes developed in conjunction with Terman and H. H. Goddard, administered the Army Alpha written mental test to recruits. Illiterate recruits and those failing the Alpha were given a picture-based test called the Army Beta.

Yerkes hoped that the army could be "engineered" by classifying the intelligence and capabilities of all recruits. To that end, recruits were graded from A through E and Yerkes recommended that they be assigned rank and tasks according to their tested ability. Although the army did not use the results uniformly, in many instances recruits for officer training were required to have an A or B grade on the Alpha. The tests results were later used in controversial ways by both Yerkes and E. G. Boring to assess average American intelligence levels (see Yerkes, 1921, 1941). Despite whatever controversy may have arisen over the years, the army continues to use testing to assess aptitudes (Jensen, 1985).

4.01.8 THE RORSCHACH INKBLOT TECHNIQUE AND CLINICAL PSYCHOLOGY

The history of the Rorschach Inkblot Technique is in many ways a reflection of the history of clinical psychology in America. Clinical psychology continues to struggle with competing world views focusing on the nature of reality, the mind, and human behavior. In clinical psychology the debate about how to view the mind and behavior is usually expressed, broadly speaking, as poles of a dimension anchored by only observable behavior at one end, the influences of conscious mental processes (i.e., cognition) more in the center, and unconscious mental processes anchoring the other end. The relative importance of observable behavior and unconscious mental processes alternate with the intellectual fashions of the times.

The role of the clinical psychologist as scientist, diagnostician, and therapist continue to change, with a growing fracture between the scientifically and the clinically oriented. A central focus of debate has to do with molar vs. molecular views of personality and the ways in which personality is assessed. Conflict over the use of the Rorschach is characteristic of the debate and perturbing in light of long-standing doubts about the psychometric adequacy and the clinical usefulness of the instrument. An additional factor in the ongoing conflict in psychology seems to be that in psychology, alas, like old soldiers, theories never die. Even if refuted, they are not replaced, they only very gradually fade away (Meehl, cited by Lykken, 1991).

4.01.8.1 The Social and Philosophical Context for the Appearance of the Rorschach

Although the Rorschach was first introduced in the United States in 1925, it was during the 1940s and 1950s that the Rorschach rose to prominence in clinical psychology. The prevailing theoretical views in American academic psychology during the early years of the Rorschach were Gestalt and behaviorism. In many ways the interest and devotion of Rorschach proponents to the technique seems to have been a reaction against what they saw as reductionist and positivistic approaches to personality assessment on the part of behaviorists and often atheoretical psychometricians. Additionally, behaviorists focused on environmental determinants of behavior at the same time that psychoanalytic theory, in spite of its rejection in much of academia, was beginning to flourish in clinical psychology. Moreover, by the late 1940s, many psychologists were interested in reviving the notion of the self, which had been rejected by behaviorism and psychoanalysis (Reisman, 1991).

Proponents of the Rorschach believed that underlying dimensions of "true" personality could be elicited only by indirect, projective methods; defense mechanisms, repression, and perhaps other unconscious processes prevented an individual from having access to critical information about him- or herself. Direct assessment of personality was narrow and incomplete, but the ambiguity of the inkblot stimulus material would elicit true responses. Because during the 1940s and 1950s testing was virtually the only applied professional activity performed by clinical psychologists (Millon, 1984), it is not surprising that the Rorschach would generate a great deal of interest and activity. What is surprising is that a test criticized even then and continuously until now as being too subjective in administration, scoring, and interpretation, of questionable reliability, and of dubious validity, would be continually used for 70 years.

Rorschach proponents did claim to view the technique as scientific, and there were attempts to establish norms and to approach the Rorschach scientifically, but we view the Rorschach ultimately as what Richard Feynman (1986) refers to as "Cargo Cult Science:"

> In the South Seas there is a cargo cult of people. During the war, they saw airplanes land with lots of good materials, and they want the same thing to happen now. So they've arranged to make things like runways, to put fires along the sides of the runways, to make a wooden hut for a man to sit on, with two wooden pieces on his head like headphones and bars of bamboo sticking out like antennas—he's the controller—and they wait for the airplanes to land. They're doing everything right. The form is perfect. It looks just the way it looked before. But it doesn't work. No airplanes land. So I call these things cargo cult science, because they follow all the apparent percepts and forms of scientific investigation, but they're missing something essential, because the planes don't land.

The Rorschach technique is missing something essential. Although as we stated earlier, people almost certainly "project" aspects of their personality on to ambiguous stimuli, use of the Rorschach has failed to demonstrate convincing evidence of validity in decades of attempts to find it. The planes still don't land.

4.01.8.2 The Birth of the Rorschach

Whether and how to use the Rorschach has been a source of controversy since its introduction. Perhaps much of the controversy and dissent about scoring and interpretation of responses to the inkblots among advocates of the technique were a result of its founder's death a few months after the publication of his initial monograph detailing 10 years of studies with inkblots, leaving a nascent method open to various interpretations. The original notions of using the technique tentatively and experimentally began fading with its founder's death, being replaced by an overriding concern for clinical uses.

Herman Rorschach, the son of a Swiss art teacher, began experimenting with inkblots in various psychopathic hospitals in 1911, the year after completing his medical training (Klopfer & Kelley, 1942). The Rorschach method was introduced in the United States in 1925 by David Levy, a psychologist and psychiatrist (Hertz, 1986; Klopfer & Kelley, 1942), who had been a student of Emil Oberholzer, Rorschach's closest medical colleague and who continued Rorschach's work after his death. Levy taught the technique to Samuel Beck, who wrote his dissertation on the technique and published the first manual on the Rorschach in 1937 (Exner, 1969; Hertz, 1986; Klopfer & Kelley, 1942). Beck and Bruno Klopfer were probably the most influential individuals in terms of widening the use of the technique, as well as in fomenting debate about how to score and interpret Rorschach responses. Beck was more behavioral and experimental in his approach and strongly advocated establishing norms and testing the validity of responses. Klopfer, a German who had studied with Jung in Switzerland after fleeing Hitler and before coming to the United States, was much more inferential in his interpretation and scoring. Rorschach himself was considerably more tentative about his findings than subsequent proponents of the technique were, or than they seem to be to this day.

It is likely that dissemination of the Rorschach was actually helped by the controversy and dissent within the ranks of Rorschach adherents, as well as by the fight against perceived rigid standards of psychometrics and nomothetic personality theories. The internal debate among adherents of various systems of scoring and interpretation seemed to foster beliefs that the findings finally proving them right were just around the corner. This belief of imminent justification seems to characterize even present day Rorschach proponents.

Another faction of Rorschach adherents with more interest in applying the Rorschach to clinical cases took the view that assessment and prediction based on clinical judgment and acumen are inherently superior to psychometric and statistical assessment and prediction. During the 1950s and 1960s, the emphasis shifted from scores and scoring systems to the utilization of clinical acumen and sensitivity, and attempts to understand subtle aspects of the entire testing situation (Sarason, 1954). As the role of the clinical psychologist expanded into more applied clinical activity, practitioners' attention to the experimental scientific roots of the discipline began fading. With this movement further from a scientific basis for theories and techniques, the theories promoted by academic psychologists were considered mechanistic by most practitioners. As a result, the academics' criticisms about projectives such as the Rorschach were increasingly viewed as invalid (or, perhaps worse, as irrelevant). In our reading of the literature, it appears that even those Rorschach supporters who believe science is important cling to the "Cargo Cult Science" of ratios and scoring systems lacking in empirical support but with the expectation of redemption almost momentarily expected.

This shift in the 1950s and 1960s to a focus on clinical skills was in the context of the emergence of psychotherapy as a primary professional activity for psychologists. Erikson's theory of psychosocial development was embraced, psychodynamic theory in various forms (Adler, Rank, Horney, Sullivan) was popular with clinicians, and Rogerian humanistic psychology emerged along with behavior modification and systematic desensitization (Reisman, 1991). In psychiatry there were rapid advances in psychotropic medications. These changes in the field seemed to steel the resolve of clinicians who believed that human psychology could not be reduced to biology, classification, and statistical formulas. Despite the lack of any demonstrated validity of the Rorschach from research studies, clinicians focused on the feedback they received, or thought they received, from clients, and believed the Rorschach helped them to better understand their clients. At about the same time as these developments, Paul Meehl (1954) published an analysis of the general problem of clinical vs. statistical prediction.

4.01.8.3 Clinical vs. Statistical Prediction

The central issue in relation to comparisons of clinical and statistical (actuarial) prediction is simple: when there is a database of cases with known outcome, can a skilled clinician use his or her judgment to combine the relevant information about a client into the correct formulations (predictions) as well as or better than a statistical formula that uses the same information? The answer, based on numerous studies in which clinicians had as much or more information as was entered into the statistical prediction, is *no*. Clinicians occasionally equal but never exceed statistical predictions of behavior, diagnoses, psychotherapy outcome, and like events of interest. The preponderance of evidence favors statistical prediction.

Even when statistical models are based upon the information used by clinicians, the models outperform the clinicians on whom they are based (Dawes et al., 1989). Exceptions do occur in circumstances of events that reverse the actuarial formula or of judgments mediated by theories that are, therefore, difficult or even impossible to duplicate statistically (Dawes et al., 1989). When such information is available to clinicians, and those circumstances may be infrequent, they are likely to outperform statistical models. Meehl (1954) referred to these rare events as the broken leg phenomenon. That name was derived from an illustration in which a statistical formula is highly successful in predicting an individual's weekly attendance at a movie, but should be discarded upon discovering that the subject is in a cast with a fractured femur.

One reason for the superiority of statistical prediction is that clinicians tend to think that too many cases are exceptions to ordinary rules and, even in the case of rare events, they ultimately perform better when they rely strictly on statistical conclusions (Goldberg, 1968). The human mind is a poor computer and does not do a good job at quantifying and weighting observations, the very things that regression equations were invented for (Goldberg, 1991). We do not mean to suggest that statistical formulas can be used to perform psychotherapy, or that the predictions could be made without first gathering the relevant observations from clinicians. We also bear in mind that a great many clinical decisions are made in circumstances in which there is no known outcome.

The debate about clinical vs. statistical prediction has been characterized by *ad hominem* attacks, and Meehl (1954) started his book, *Clinical versus statistical prediction,* with lists of invective from both sides of the argument. Briefly, opponents of statistical prediction have suggested that the approach is atomistic, inhuman, arbitrary, and oversimplified, while its proponents suggest that it is objective, reliable, rigorous, and scientific. Conversely, negative appraisals of clinical prediction suggest the method is sloppy, muddleheaded, unscientific, and vague, while its proponents suggest that the method is dynamic, sensitive, meaningful, and holistic (Meehl, 1954).

The case for the use of psychodiagnostic tests such as the Rorschach and the validity of clinical observation of relationships between thoughts, behavior, and personality characteristics becomes questionable considering the findings about the questionable validity of clinical judgments. Further, it has been known for a long while that statements from clinical assessments and psychological reports are often of universal applicability (Forer, 1949). When previously prepared statements representative of those in psychological evaluations are presented to a variety of individuals, the individuals enthusiastically agree that the statements uniquely apply to them. Therefore, it seems that the very evidence often used by clinicians, that their clients believe assessments to be accurate and that they are helped by assessment and treatment, affords no reassurance. Much information provided by typical psychodiagnostic feedback is general and applies to almost anyone. The associations with various personality characteristics, signs, and indicators may be more related to what any astute observer has learned to associate with them through observation, folklore, and literature, that is, "illusory correlations" (Chapman & Chapman, 1967, 1969; Reisman, 1991). It is likely that such illusory correlations are involved in accounts of individuals known as "Rorschach Savants," who are purported anecdotally to see phenomenal amounts of information in Rorschach responses.

It is astonishing that the Rorschach continues to be not only very popular, but in many states is required as part of forensic psychological assessment in child custody disputes (Robyn Dawes, personal communication). Reisman (1991) suggests that the failure of clinical psychologists to modify their behavior no matter how much aversive stimulation is applied is less a refutation of Skinner's theory than evidence of a great capacity to distort information. Many clinicians and even some researchers continue to believe in the validity of the Rorschach (and other projective tests) in spite of overwhelming evidence to the contrary and almost universal agreement among the scientific community that the central assumption on which the Rorschach is based is faulty.

> The entire Rorschach is based on a fallacious assumption, namely that indirect (projective) methods are more valid than direct (self-rating or questionnaire) methods because people are so repressed that they cannot describe their real emotions and impulses. A large body of literature indicates the fallacy of this assumption. Even within self-report items, more content obvious items prove to be more valid than subtle ones. Why give an hour test, with another hour to score, to get a crude estimate of anxiety or depression which is usually less reliable and valid than a short true–false scale which takes a few minutes and where there is no unreliability of scoring? I have compared direct and indirect (Rorschach and TAT) measures of dependency, anxiety, depression, and hostility using peer ratings as criteria. The most indirect methods have zero validity, the most direct methods have low to moderate validity, and methods which are intermediate in directness (e.g., sentence completion) are intermediate in validity. A great deal of effort was expended in scoring content from TAT and Rorschach and consensus agreement was obtained where disagreement in scoring occurred. All this was to no avail because the two projectives did not correlate with each other let alone with the criteria or any of the direct methods. (Marvin Zuckerman, SSCPNET, April 22, 1996)

Although yet another scoring system for the Rorschach has been used and researched for the past 20 years (Exner, 1974, 1993) with a greater emphasis on standardization of scoring and interpretation, it has yielded no apparent improvement on the predictive or incremental validity of the technique. Criticisms of the research are nearly identical to those expressed in the 1940s and 1950s. Disturbingly, in spite of overwhelming evidence of their invalidity, clinicians tend to continue to rely on their impressions and interpretations of the content of Rorschach responses (Reisman, 1991). It is not precisely fair to say that the Rorschach is unrelated to anything, but its validity is so limited as to leave virtually no real utility for its use. Most problematic, it is inferior to and more time-consuming than instruments with better reliability and validity and the Rorschach appears to have zero incremental validity (Sechrest, 1963).

4.01.8.4 Old Tests Never Die, They Just Fade Away

The continued drift of psychology away from its scientific roots does not appear to be slowing. This drift seems additionally fueled by economic and employment concerns and continued training of too many practitioners. The current conflict is unlikely to slow as managed health care and cutbacks in federal funding lessen job opportunities, and the future of psychology is uncertain. Clinical psychology, even in the halcyon days of the scientist–practitioner model, was never resolute in its commitment to science. For example, students coming into the field were generally not required to have any particular prior training in science, or its principal handmaiden, mathematics, and they needed only to declare a personal fealty to the idea of research. That situation has almost certainly become much worse over the past two or three decades of drift toward practitioner–scientist, then practitioner–scholar, and then frankly practitioner programs. The net result is that clinical psychology has a huge number of practitioners who are not only ill-equipped to handle the demands of evaluating the scientific basis for practice, but they are ill-disposed even to doing so. Economic pressures and their own incapacities make scientific evidence, which is at best likely to be disappointing, a threat. Anecdotes, "clinical experience," and so on are far more reassuring and, hence, attractive. Better to believe in an unproven instrument or procedure than to be deprived of any basis for pride and survival.

Lykken (1991) noted that present knowledge in psychology is very broad but very shallow. Most recently trained clinical psychologists probably have little acquaintance with the philosophy of science and not much knowledge of the clinical vs. statistical prediction literature; certainly they have inadequate training in measurement, statistics, and probability. This ignorance of the roots of psychological theory and scientific psychology contributes to the continued use of a completely unjustifiable procedure such as the Rorschach. It is difficult to refute disproven techniques and theories when a class of the profession basis its identity and livelihood on them. The problem of theories fading away and reviving as suggested by Meehl's "old soldiers" simile is not restricted to clinical psychology; psychology as a whole operates in this way.

In other sciences, each generation builds on the foundations of the discipline's previous scientists. Psychology seems to view its predecessors as "intrepid explorers who came back empty-handed" (Lykken, 1991). To be fair, establishing a psychological science is extremely difficult because it is difficult to operationalize psychological constructs and because there is notable measurement error. The profession and practice of clinical psychology would be helped immensely, however, if we could better educate graduate students in philosophy of science, measurement, and statistics, in addition to psychological theory.

The Rorschach did not come into prominence originally because of evidence for its superiority over existing measures, for example, questionnaires and checklists. It was adopted eagerly, we think, more because of discontent with the obvious inadequacies of existing alternatives. We suspect that whatever its own inadequacies, the Rorschach will not die but will only fade away when some alternative instrument or procedure becomes available and seems potentially to be a better one.

4.01.9 OTHER MEASURES USED IN CLINICAL PSYCHOLOGY

The list of measures that have been used in clinical psychology is very long, and many appear simply to have faded away. For example, two projective tests that once had a spate of popularity are the Blacky Test and the Make-a-Picture Story Test (MAPS) (Shneidman, 1986). The Blacky Test seems to have disappeared altogether, and the MAPS is rarely encountered in the literature. Neither was ever demonstrated to be less reliable or less valid than other tests; each simply appears to have faded away, the Blacky probably because its version of psychoanalytic theory has also faded somewhat and the MAPS because it was cumbersome and slow to administer. There is not much point in recounting the histories of the many now deservedly (even if not uniquely deserved) forgotten tests.

4.01.9.1 The Thematic Apperception Test

Morgan and Murray (1935) introduced the Thematic Apperception Test (TAT) based on what they termed the "well-recognized fact" that when presented with ambiguous stimuli people reveal their own personality. The TAT consists of a series of pictures of ambiguous social situations in which the examinee describes the social situation as they see it. The TAT was originally designed to be interpreted in light of psychoanalytic theory, the theory driving its design. There were subsequently a variety of scoring systems from different perspectives, although none has improved on the recurrent problem of inconsistency in use from clinician to clinician.

The TAT, as one might imagine, can be scored more or less reliably, depending on the nature of the variable involved and the adequacy of its definition. The major problem is what the scores may be related to and how they may be interpreted. Over the many years of its existence, TAT scores have been related to many different phenomena, sometimes with moderate success. The literature would show that achievement has been extensively studied by way of the TAT (see Keiser & Prather, 1990) as have other needs or motives. Although the research is reasonably consistent in showing some evidence for validity of some TAT scores and the instrument has proven to be of some value in research, the evidence was never strong enough to justify use of the TAT for individual decision-making in clinical settings. The TAT, like most other clinical measures, can at best be considered enlightening.

4.01.9.2 Sentence Completion Tests

Another variety of quasiprojective instruments is the sentence completion test, which consists of a stem, for example, "When I was a child," that the respondent is supposed to make into a complete sentence by writing down his or her own thoughts. The sentence completion test, of which the Rotter Incomplete Sentences Blank (Rotter & Rafferty, 1950) is the best known version, probably evolved from word association tests, which go back to Galton, Cattell, and Kraepelin in the latter part of the nineteenth century (Anastasi, 1988). The Rotter ISB was considered to be a measure of psychological conflict and, therefore, adjustment, and like so many other measures, under the right circumstances, it could be scored in a reasonably dependable way and could result in "significant" validity coefficients. That is to say, the ISB could be shown variously and not invariably to be correlated around 0.30 with criteria thought by someone to be of interest. Those correlations might be useful for some research purposes, but they were not grounds for much confidence in clinical settings. They may, however, in the minds of many clinicians have inspired more confidence and, therefore, more use than was warranted.

4.01.9.3 Objective Testing

The term "objective test" usually refers to a self-report measure that presents a stimulus item to a respondent and that requires a constrained response such as "True/False," "Agree/Disagree," and so forth. There are many, many objective tests, but the dominant one is, and virtually always has been, the MMPI (Hathaway & McKinley, 1943). We have already discussed various aspects of the MMPI under other topics, but it is worth noting here that the durability of the MMPI has been impressive. Its clinical utility has not. It yields profiles that seem impressive, and it certainly can, in general, serve as a screening instrument for psychopathology: people who get really high scores on one or more of the MMPI scales probably have *something* awry in their lives. No relationships have ever been consistently demonstrated between the MMPI and functional capacities or incapacities that would justify clinical decisions other than to seek further information about the client or patient.

The MMPI more than other available instruments has been automated, to the extent of producing computer-based interpretations of test profiles. An unfortunate limitation of computer-based interpretations is that, because of their proprietary nature, the algorithms underlying them are not available. Consequently, one cannot know which interpretations are based on empirical evidence and which, perhaps, on clinical lore, let alone how good the evidence might be. Such interpretations must be accepted on faith. When the MMPI is used in a fully automatic mode, it is questionable whether it even should be considered a clinical assessment.

4.01.9.4 The Clinician as a Clinical Instrument

Clinical psychology has never been completely clear about whether it wishes to distinguish between the test—a tool—and the test-in-the-hands-of-a-user. The perspective of standardized testing implies that the test is a tool that, in the hands of any properly trained user, should produce the same results for any given examinee. Many clinical instruments, however, cannot be considered to be so tightly standardized, and it is to be expected that results might differ, perhaps even substantially, from one examiner to another, even for the same examinee. Within reason, at least, an examinee's performance on a vocabulary test or a trail-making test should be little affected by the characteristics of the examiner, nor should the scoring and interpretation of the performance. By contrast, an examinee's responses might be affected to a considerable degree by the characteristics of an examiner administering a Rorschach or a TAT, let alone the interpretation of those responses.

The field of clinical psychology abounds in tales of diagnostic acumen of marvelous proportions manifested by legendary clinicians able to use the Rorschach, an MMPI profile, or some other instrument as a stimulus. Unfortunately, no such tales have advanced beyond the bounds of anecdote, and none of these legendary clinicians appears to have been able to pass along his or her acumen to a group of students—let alone passing it along across several generations. Consequently, if clinicians are to be part of the clinical assessment equation, then it seems inevitable that individual clinicians will have to be validated individually, that is, individual clinicians will have to be shown to be reliable and valid instruments. That will not further progress in the field.

4.01.9.5 Structured Interviews

A fairly recent development in clinical assessment is the structured interview schedule. These schedules are intended to produce a diagnostic judgment related to the *DSM* (American Psychiatric Association, 1994), a narrow, bounded purpose. There are several such interview schedules currently available, but we will discuss the Structured Clinical Interview for *DSM-IV* (SCID) as an example and because it is probably the one most widely used.

As noted earlier, most psychological assessment appears to be done for purposes of enlightenment rather than for decision-making. Nevertheless, diagnoses are often required for reimbursement, medication referrals, custody evaluations, and forensic assessments. The SCID (Spitzer, Gibbon, & Williams, 1997) appears to be used quite infrequently in other than research settings, for example, it is not mentioned on any list of instruments used by clinicians. That neglect is interesting in view of the attention that was paid to the development of the SCID and its established dependability.

Use of the SCID in clinical practice would probably contribute to improved assessment (and presumably to more appropriate treatment), whether for specific *DSM* diagnostic purposes or simply for gathering pertinent information. The SCID was designed to capitalize on clinical skills and to be more "clinician-friendly" than other structured interviews (Spitzer, Williams, Gibbon, & First, 1992). The SCID is meant to be used by precisely those people who can already conduct an interview, and although the SCID is somewhat time-consuming, but probably less so than, say, the Rorschach, psychologists interview all patients, and for most clinicians to do so in a structured manner would not be a significant departure. That is, the time would be spent interviewing the patient and the SCID would not add much if anything in terms of time or cost to standard practice. The SCID demonstrates good reliability (test–retest and inter-rater) for most disorders, with kappa coefficients averaging 0.60–0.80 or greater (Segal, Hersen, & Van Hasselt, 1995; Williams, Gibbon, First, & Spitzer, 1992). Agreement between diagnoses obtained by SCID and by traditional clinical interviews is poor to moderate with average kappa coefficients of 0.25 (Steiner, Tebes, Sledge, & Walker, 1995), suggesting strongly that reliance on unstructured clinical interviews is unwise.

Perhaps the SCID is not used because it takes some training and practice to become proficient in its use. That requirement is certainly different from the typical assessment instruments advertised in psychological publications, which boast their quick and easy use and say nothing about their reliability and validity. It may also be that beliefs about the superiority of clinical judgment over other more structured practices, for example, the use of projective tests, contributes strongly as well. Whatever the reasons for lack of clinical use of the SCID, and we suspect that it is both training time and beliefs about clinical skill, it is an unfortunate omission from assessment practice.

4.01.10 CONCLUSIONS

Progress in psychological assessment, at least for clinical applications, has been disappointing over the century since the field started. Conceptual and theoretical developments have been minimal, although we might except some observational methods used primarily in behavioral work and some research settings. The field continues to move away from its scientific roots in psychology, and clinical assessment has no other base on which to build any conceptual structure. Moreover, clinical assessment has never been more than minimally guided by psychometric theory and analysis, for example, scarcely beyond superficial concern with "reliability" of measures, and graduate education and training in research methods and measurement is at an ebb and is maybe still decreasing. Overall, clinical assessment as an enterprise seems to be cut adrift from any important sources of rigor, and almost anything goes. Perhaps it is fortunate, then, that despite the frequent insistence on assessment as a cornerstone of the practice of clinical psychology, there is much less evidence for its importance and prevalence than would be expected.

4.02.1 INTRODUCTION

Measurement is a set of rules for assigning numbers to objects or entities. A psychological measuring device (typically a test), then, is a set of rules (the test questions, directions for administration, scoring criteria, etc.) for assigning numbers to an individual that are believed to represent a level of some particular psychological trait, attribute, or behavior of the individual. These characteristics may be observable directly or may be inferred or observed indirectly through changes in behavior or responses to a set or a variable stimulus. Assessment is a more comprehensive process of deriving meaning from test scores and clinical information in order to describe the individual both broadly and in depth. Psychological tests are the nonexclusive tools of assessment. A proper assessment must also consider the background and current cultural milieu of the individual and actual observed behavior. This chapter does not attempt to deal with all aspects of the assessment process. An introduction to basic measurement technology and theory will be provided along with material concerning different methods of measurement intended to enhance understanding of other chapters in this work.

There are many problems and controversial issues in psychological and educational assessment and, obviously, all cannot be treated in this work. As one example, assessment and the testing that accompanies it occur within a particular situation or context. The results that are obtained may thus be strongly influenced by situational factors in the case of some individuals but less so or not at all for others. The question of the generalizability of test results obtained under a specified set of conditions takes on major importance in interpreting test scores. Not all variables that influence generalizability are known and few that are have been well researched. Test anxiety is one factor thought to influence strongly the generalizability of results across settings and has been researched extensively, yet the complete articulation of the relationship among test anxiety, test performance, and the validity of test-score interpretations across settings is far from complete. The assessment of children, in particular, poses special problems because of the rapid growth and development as well as their susceptibility to external environmental factors. Many of these factors are treated at length in Anastasi (1981), Cronbach (1983), Kaufman (1994), Reynolds (1985), and Reynolds and Kamphaus (1990a, 1990b), and the interested reader is referred to these sources for further reading on the problems, issues, and limitations of educational and psychological testing, as well as to the other chapters in this volume and to Volume 10.

4.02.2 NORMS AND SCALES OF MEASUREMENT

Many pieces of information are necessary before one can attach the proper meaning to a test score. Among the basic are knowledge of what scale of measurement has been employed and with what sort of reference group the individual is being compared, if any. Different scales have different properties and convey different levels and types of information just as they do in other arenas; for example, four inches of water conveys a very different meaning than a reference to four gallons of water. The four basic scales of measurement are nominal, ordinal, interval, and ratio scales. As one moves from nominal scales toward ratio scales, increasingly sophisticated levels of measurement are possible.

4.02.2.1 Scales of Measurement

4.02.2.1.1 Nominal scales

A nominal scale is a qualitative system of categorizing people (or objects, traits, or other variables) or individual observations regarding people typically into mutually exclusive classes or sets. Sex is an example of a nominal scale; one is either male or female. Diagnostic categories such as hyperactivity, learning disabled, aphasia, severely emotionally disturbed, or major depressive disorder represent nominal scaling categories that are not mutually exclusive. Nominal scales provide so little quantitative information about members of categories that some writers prefer to exclude nominal scales from the general rubric of measurement. As Hays (1973) points out, the term measurement typically is reserved for a situation where each individual is assigned a relational number. Because the quantitative relationship among nominal categories is unknown, many common statistical tests cannot be employed with nominal scale data. However, since nominal scales do allow for the classification of an event into a discrete category, many writers (e.g., Nunnally, 1978) do include them as one type of measurement.

4.02.2.1.2 Ordinal scales

Ordinal scales provide considerably more quantitative information regarding an observation than nominal scales. Ordinal scales allow one to rank objects or people according to the amount of a particular attribute displayed. Ordering usually takes the form of the "most" to the "least" amount of the attribute in question. If children in a classroom were weighed and then ranked from heaviest to lightest with the heaviest child assigned the rank of 1, the next heaviest a 2, and so on, until all children had been assigned a number, the resulting measurement would be on an ordinal scale. Although an ordinal scale provides certain quantitative information about each individual, it does not tell how far apart each observation is from the next one. Between adjacent pairs of ranks there may be a different degree of difference. The difference in weight between child 1 and child 2 may be 10 pounds, but the difference between child 2 and child 3 may be one pound or even less. Ordinal scales thus designate relative positions among individuals, an advance over nominal scaling, but are still crude with regard both to describing individuals and to the possible statistical treatments that can be meaningfully applied. Means and standard deviations are usually without meaning when applied to ordinal scales, although the median and mode can be determined and used meaningfully. Age and grade equivalents are examples of common ordinal scales.

4.02.2.1.3 Interval scales

Interval scales afford far more information about observations and can be mathematically manipulated with far greater confidence and precision than nominal or ordinal scales. To have an interval scale of measurement, one must have an ordinal scale on which the difference between any two adjacent points on the scale is equal. Most of the measurement scales and tests used in psychology and education assume an interval scale. Intelligence tests are one good example of an interval scale and can also illustrate the distinction between interval and the highest level of measurement, ratio scales. Although nearly all statistical methods can be applied to measurements on an interval scale, the interval scale has no true zero point, where zero designates total absence of an attribute. If one were to earn an IQ of zero on an intelligence test (by failing to answer a single question correctly), this would not indicate the absence of intelligence, for without intelligence no human could remain alive (it is not possible on most tests of intelligence to earn an IQ of zero even if all test questions are answered incorrectly).

4.02.2.1.4 Ratio scales

Ratio scales possess the attributes of ordinal and interval scales but also have a true zero point—a score of zero indicates the complete absence of the attribute under consideration. Length and width are ratio scales. There are few instances of ratio scales in psychology outside of measurement of simple sensory and motor functions. Ratio scales have useful quantitative features, in particular, as indicated by the name: ratios are meaningful—six feet is twice three feet. Ratios are not meaningful with interval scales. A person with an IQ of 100 cannot be said to be twice as intelligent as a person with an IQ of 50. Fortunately, it is not necessary to have ratio scales to attack the vast majority of problems in psychological assessment.

This discussion of scales of measurement has necessarily been limited to the most basic elements and distinctions among scales. The reader who desires to explore this topic from a technical perspective will find an excellent and extensive mathematical presentation of scales of measurement in Hays (1973).

4.02.2.2 Norms and Reference Groups

To understand the individual's performance as represented by a score on a psychological measurement device, it is necessary, except with certain very specific tests, to evaluate the individual's performance relative to the performance of some preselected group. To know simply that an individual answers 60 out of 100 questions correctly on a history test, and 75 out of 100 questions correctly on a biology test, conveys very little information. On which test did this individual earn the better score? Without knowledge of how a comparable or other relevant group of persons would perform on these tests, the question of which score is better cannot be answered.

Raw scores on a test, such as the number or percentage of correct responses, take on meaning only when evaluated against the performance of a normative or reference group of individuals. For convenience, raw scores are typically converted to a standard or scaled score and then compared against a set of norms. The reference group from which the norms are derived is defined prior to the standardization of the test. Once the appropriate reference population has been defined, a random sample is tested, with each individual tested under as nearly identical procedures as possible. Many factors must be considered when developing norms for test interpretation. Ebel (1972), Angoff (1971), and Petersen, Kolen, and Hoover (1989) have provided especially good discussions of the necessary conditions for appropriate development and use of normative reference data. The following points are taken principally from these three sources, with some elaboration by the present author. Some of these conditions place requirements on the test being normed, some on the psychological trait being measured, and others on the test user.

(i) The psychological trait being assessed must allow the ranking of individuals along a continuum from high to low, that is, it must be amenable to at least ordinal scaling. If a nominal scale was employed, only the presence or absence of the trait would be of interest and relative amounts of the trait could not be determined; norms, under this unusual condition, would be superfluous if not distracting or misleading.

(ii) The content of the test must provide an adequate operational definition of the psychological trait under consideration. With a proper operational definition, other tests can be constructed to measure the same trait and should yield comparable scores for individuals taking both tests.

(iii) The test should assess the same psychological construct throughout the entire range of performance.

(iv) The normative reference group should consist of a large random sample representative of the population on whom the test is to be administered later.

(v) The normative sample of examinees from the population should "have been tested under standard conditions, and ... take the test as seriously, but no more so, than other(s) to be tested later for whom the norms are needed" (Ebel, 1972, p. 488).

(vi) The population sampled to provide normative data must be appropriate to the test and to the purpose for which the test is to be employed. The latter point is often misinterpreted, especially with regard to evaluation of exceptional children. Many adequately normed psychological tests are inappropriately maligned for failure to include significant numbers of handicapped children in their normative sample. The major intelligence scales designed for use with children (i.e., the various Wechsler scales and the McCarthy Scales of Children's Abilities) have been normed on stratified random samples of children representative of children in the United States. Some authors (e.g., Salvia & Ysseldyke, 1981) criticize tests such as the Wechsler scales as inappropriate for measuring the intellectual level of various categories of children with disabilities because large numbers of these children were not included in the test's standardization sample. Whether this is a valid criticism depends on the purpose to which the test is applied. If knowledge of an emotionally disturbed child's level of intellectual functioning relative to age mates in the United States is desired, comparing the child's performance to that of other similarly emotionally disturbed children, then a reference group of emotionally disturbed children would be appropriate. The latter information is not sought frequently nor has it been shown to be more useful in the diagnosis or development of appropriate intervention strategies. Salvia and Ysseldyke (1981) contend that it would be inappropriate to base predictions of future intellectual or academic performance on test scores for an exceptional child that have been derived through comparison with the larger, normal population's performance. To make predictions, they would first require that the reference group from which scores are derived be a group of similar sociocultural background, experience, and handicapping condition. Although this may be an appropriate, if not noble, hypothesis for research, implementation must await empirical verification, especially since it runs counter to traditional psychological practice. Indeed, all interpretations of test scores should be guided principally by empirical evidence. Once norms have been established for a specific reference group, the generalizability of the norms becomes a matter of actuarial research; just as norms based on one group may be inappropriate for use with another group, the norms may also be appropriate and *a priori* acceptance of either hypothesis would be incorrect (Reynolds & Brown, 1984). A large, cumulative body of evidence demonstrates clearly that test scores predict most accurately (and equally well for a variety of subgroups) when based on a large, representative random sample of the population, rather than open highly specific subgroups within a population (e.g., Hunter, Schmidt, & Rauschenberger, 1984; Jensen, 1980; Reynolds, 1982, 1995, in press-a, in press-b).

(vii) Normative data should be provided for as many different groups as it may be useful for an individual to be compared against. Although this may at first glance seem contradictory to the foregoing conclusions, there are instances when it is useful to know how a patient compares to members of other specific subgroups. The more good reference groups available for evaluating a patient's performance on a test, the potentially more useful the test may become.

The normative or reference group most often used to derive scores is the standardization sample, a sample of the target population drawn using a set plan. The best tests, and most publishers and developers of tests, aspire to a standardization sample that is drawn using population proportionate stratified random sampling. This means that samples of people are selected based on subgroups of a larger group to ensure that the population as a whole is represented. In the USA, for example, tests are typically standardized via a sampling plan that stratifies the sample by gender, age, ethnicity, socioeconomic background, region of residence, and community size based on population statistics provided by the US Bureau of the Census. If the Census Bureau data were to indicate, for example, that 1% of the US population consisted of African-American males in the middle range of socioeconomic status residing in urban centers of the south region, then 1% of the standardization sample of the test would be drawn to meet this same set of characteristics.

Once the normative reference group has been obtained and tested, tables of standardized or scaled scores are developed. These tables are based on the responses of the standardization sample and are frequently referred to as norms tables. There are many types of scaled scores or other units of measurement that may be reported in the "norms tables" and just which unit of measurement has been chosen may greatly influence score interpretation.

4.02.3 UNITS OF MEASUREMENT

Raw scores such as number correct are tedious to work with and to interpret properly. Raw scores are thus typically transformed to another unit of measurement. Scaled scores are preferred, but other units such as age and grade equivalents are common. Making raw scores into scaled scores involves creating a set of scores with a predetermined mean and standard deviation that remain constant across some preselected variable such as age.

The mean is simply the sum of the scores obtained by individuals in the standardization sample divided by the number of people in the sample ($\Sigma X_i/N$). In a normal distribution of scores (to be described in the next paragraph), the mean breaks performance on the test into two equal parts, with half of those taking the test scoring above the mean and half scoring below the mean, though the *median* is formally defined as the score point which breaks a distribution into two equal parts; in a normal distribution, the mean and median are the same score.

The standard deviation (SD) is an extremely useful statistic in describing and interpreting a test score. The SD is a measure of the dispersion of scores about the mean. If a test has a mean of 100 and an individual earns a score of 110 on the test, we still have very little information except that the individual performed above average. Once the SD is known, one can determine how far from the mean the score of 110 falls. A score of 110 takes on far different meaning depending on whether the SD of the scores is 5, 15, or 30. The SD is relatively easy to calculate once the mean is known; it is determined by first subtracting each score from the mean, squaring the result, and summing across individuals. This sum of squared deviations from the mean is then divided by the number of persons in the standardization sample. The result is the variance of the test scores; the square root of the variance is the SD.

Once the mean and SD of test scores are known, an individual's standing relative to others on the attribute in question can be determined. The normal distribution or normal curve is most helpful in making these interpretations. Figure 1 shows the normal curve and its relationship to various standard score systems. A person whose score falls 1 SD above the mean performs at a level exceeding about 84% of the population of test-takers. Two SDs will be above 98% of the group. The relationship is the same in the inverse below the mean. A score of 1 SD below the mean indicates that the individual exceeds only about 16% of the population on the attribute in question. Approximately two-thirds (68%) of the population will score within 1 SD of the mean on any psychological test.

Standard scores such as those shown in Figure 1 (*z* scores, *T* scores, etc.) are developed for ease of interpretation. Though standard scores are typically linear transformations of raw scores to a desired scale with a predetermined mean and SD, normalized scaled scores can also be developed. In a linear transformation of test scores to a predetermined mean and SD, equation (1) must be applied to each score:

$$\text{scaled score} = X_{ss} + \mathrm{SD}_{ss}\,\frac{(X_i - X)}{\mathrm{SD}_x} \qquad (1)$$

where X_i = raw score of any individual i, X = mean of the raw scores, SD_x = standard deviation of the raw scores, SD_{ss} = standard deviation scaled scores are to have, and X_{ss} = mean scaled scores are to have.

Virtually all tests designed for use with children along with most adult tests standardize scores and then normalize them within age groups so that a scaled score at one age has the same meaning and percentile rank at all other ages. Thus a person age 10 who earns a scaled score of 105 on the test has the same percentile rank within his or her age group as a 12-year-old with the same score has in his or her age group. That is, the score of 105 will fall at the same point on the normal curve in each case.

Not all scores have this property. Grade and age equivalents are very popular types of scores that are much abused because they are assumed to have scaled score properties when in fact they represent only an ordinal scale. Grade equivalents ignore the dispersion of scores about the mean although the dispersion changes from age to age and grade to grade. Under no circumstances do such equivalent scores qualify as standard scores. Consider the calculation of a grade equivalent. When a test is administered to a group of children, the mean raw score is calculated at each grade level and this mean raw score then is called the "grade equivalent" score for a raw score of that magnitude. If the mean raw score for beginning fourth graders (grade 4.0) on a reading test is 37, then any person

earning a score of 37 on the test is assigned a grade equivalent score of 4.0 regardless of the person's age. If the mean raw score of fifth graders (grade 5.0) is 38, then a score of 38 would receive a grade equivalent of 5.0. A raw score of 37 could represent a grade equivalent of 4.0, 38 could be 5.0, 39 could be 5.1, 40 be 5.3, and 41, 6.0. Thus, differences of one raw score point can cause dramatic differences in the grade equivalents received, and the differences will be inconsistent across grades with regard to the magnitude of the difference in grade equivalents produced by constant changes in raw scores.

Table 1 illustrates the problems of using grade equivalents to evaluate a patient's academic standing relative to his or her peers. Frequently in both research and clinical practice, children of normal intellectual capacity are diagnosed as learning disabled through the use of grade equivalents such as "two years below grade level for age" on a test of academic attainment. The use of this criterion for diagnosing learning disabilities or other academic disorders is clearly inappropriate (Reynolds, 1981a, 1985). As seen in Table 1, a child with a grade equivalent score in reading two years below the appropriate grade placement for age may or may not have a reading problem. At some ages this is within the average range, whereas at others a severe reading problem may be indicated.

Grade equivalents tend to become standards of performance as well, which they clearly are not. Contrary to popular belief, grade equivalent scores on a test do not indicate what level of reading text a child should be using. Grade equivalent scores on tests simply do not have a one-to-one correspondence with reading series placement or the various formulas for determining readability levels.

Grade equivalents are also inappropriate for use in any sort of discrepancy analysis of an individual's test performance, diagnosis of a learning disability or developmental disorder, or for use in many statistical procedures for the following reasons (Reynolds, 1981a).

(i) The growth curve between age and achievement in basic academic subjects flattens at upper grade levels. This can be seen in Table 1 where there is very little change in standard score values corresponding to two years below grade level for age after about grade 7 or 8. In fact, grade equivalents have almost no meaning at this level since reading instruction typically stops by high school. Consider the following analogy with height as an age equivalent. Height can be expressed in age equivalents just as reading can be expressed as grade equivalents. It might be helpful to describe a tall first grader as having the height of an 8½ year old, but what happens to the 5 feet, 10 inch tall 14-year-old female since at no age does the mean height of females equal 5 feet, 10 inches? Since the average reading level in the population changes very little after junior high school, grade equivalents at these ages become virtually nonsensical with large fluctuations resulting from a raw score difference of two or three points on a 100-item test.

(ii) Grade equivalents assume that the rate of learning is constant throughout the school year and that there is no gain or loss during summer vacation.

(iii) Grade equivalents involve an excess of extrapolation, especially at the upper and lower ends of the scale. However, since tests are not administered during every month of the school year, scores between the testing intervals (often a full year) must be interpolated on the assumption of constant growth rates. Interpolations between sometimes extrapolated values on an assumption of constant growth rates is a somewhat ludicrous activity.

(iv) Different academic subjects are acquired at different rates and the variation in performance varies across content areas so that "two years below grade level for age" may be a much more serious deficiency in math than in reading comprehension.

(v) Grade equivalents exaggerate small differences in performance between individuals and for a single individual across tests. Some test authors even provide a caution on record forms that standard scores only, and not grade equivalents, should be used for comparisons.

Age equivalents have many of the same problems. The standard deviation of age equivalents varies substantially across tests, subsets, abilities, or skills assessed, and exist on an ordinal, not interval scale. It is inappropriate to add, subtract, multiply, or divide age or grade equivalents or any other form of ordinal score. Nevertheless, the use of such equivalent scores in *ipsative* analysis of test performance remains a common mistake in clinical, educational, and neuropsychological assessment.

The principal advantage of standardized or scaled scores lies in the comparability of score interpretation across age. By standard scores of course, I refer to scores scaled to a constant mean and SD such as the Wechsler Deviation IQ and not to ratio IQ types of scales employed by the early Binet and original Slosson Intelligence Test, which give the false appearance of being scaled scores. Ratio IQs or other types of quotients have many of the same problems as grade equivalents and should be avoided for many of these same reasons. Standard scores of the deviation IQ type have the same percentile rank across age since they

are based not only on the mean but the variability in scores about the mean at each age level. For example, a score that falls two-thirds of a SD below the mean has a percentile rank of 25 at every age. A score falling two-thirds of a grade level below the average grade level or an age equivalent six months below chronological age have different percentile ranks at every age.

Standard scores are more accurate and precise. When constructing tables for the conversion of raw scores into standard scores, interpolation of scores to arrive at an exact score point is typically not necessary, whereas the opposite is true of age and grade equivalents. Extrapolation is also typically not necessary for scores within 3 SDs of the mean, which accounts for more than 99% of all scores encountered.

Scaled scores can be set to any desired mean and standard deviation, with the fancy of the test author frequently the sole determining factor. Fortunately, a few scales can account for the vast majority of standardized tests in psychology and education. Table 2 illustrates the relationship between various scaled score systems. If reference groups are comparable, Table 2 can also be used to equate scores across tests to aid in the comparison of a patient's performance on tests of different attributes, provided normalized scores are provided.

What has been said thus far about scaled scores and their equivalency applies primarily to scores that have been forced to take the shape of the Gaussian or bell curve. When test-score distributions derived from a standardization sample are examined, the scores frequently deviate significantly from normal. Often, test developers will then transform scores, using one of a variety of statistical methods (e.g., see Lord & Novick, 1968, for a mathematical review and explication), to take a normal distribution. Despite what is often taught in early courses in psychological statistics and measurement, this is not always appropriate. It is commonplace to read that psychological variables, like most others, are normally distributed within the population; many are. Variables such as intelligence, memory skill, and academic achievement will closely approximate the normal distribution when well measured. However, many psychological variables, especially behavioral ones such as aggression, attention, and hyperactivity, deviate substantially from the normal curve within the population of humans.

When a score distribution then deviates from normality, the test developer is faced with the decision of whether to create normalized scores via some transformation or to allow the distribution to retain its shape with perhaps some smoothing to remove irregularities due to sampling error. In the later case, a linear transformation of scores is most likely to be chosen.

To make this determination, the test developer must ascertain whether the underlying construct measured by the test is normally distributed or not and whether the extant sample is adequate to estimate the distribution, whatever its shape. For applied, clinical devices, the purpose of score transformations that result in normalization of the distribution is to correct for sampling error and presumes that the underlying construct is, in fact, normally or near normally distributed. Normalization of the score distribution then produces a more

[a] *X* = mean; SD = standard deviation.

accurate rendition of the population distribution and improves the utility of the standardized scaled scores provided. If the population distribution of the construct in question is not normal, for example, aggressive behavior (see Reynolds & Kamphaus, 1992), then a different form of transformation, typically linear, is required to be accurate. This decision affects how clinicians best interpret the ultimately scaled scores.

If score distributions have been normalized for a battery of tests or subtests of a common test, for example, the Wechsler scales, the same scaled score on any part-test will have the same percentile rank. On the Wechsler Intelligence Scale for Children-III (WISC-III; Wechsler, 1992), for example, a subtest scaled score of 13 is 1 SD above the mean and, for all 13 subtests of the WISC-III, will have a percentile rank of approximately 86. If the scores had not been transformed through the nonlinear methods necessary to approximate a normal distribution, this would not be true. For a linear transformation, a scaled score of 13 could still be 1 SD above the mean on all of the subtests but the percentile rank could vary, and could vary substantially the more the underlying distribution deviates from that of the normal curve. It is thus important for clinicians to review test manuals and ascertain the methods of scaling that have been applied to the raw score distributions. This becomes increasingly important as scores are to be compared across different tests or batteries of tests. This effect is magnified as the distance from the mean increases.

4.02.4 ACCURACY OF TEST SCORES

4.02.4.1 True Score Theory

When evaluating test scores, it is also necessary to know just how accurately the score reflects the individual's true score on the test. Tests typically do not ask every possible question that could be asked or evaluate every possible relevant behavior. Rather a domain of possible questions or test items is defined and a sample taken to form the test. Whenever less than the total number of possible behaviors within a domain is sampled, sampling error occurs. Psychological and educational tests are thus destined to be less than perfect in their accuracy. Certainly, psychological tests contain errors produced from a variety of other sources, most of which are situational. Error resulting from domain sampling is the largest contributor to the degree of error in a test score, however (Feldt & Brennan, 1989; Nunnally, 1978), and is the type of error about which measurement theory has the greatest concern. Fortunately, this type of error is also the easiest and most accurately estimated.

Error caused by domain sampling is determined from an analysis of the degree of homogeneity of the items in the test, that is, how well the various items correlate with one another and with an individual's true standing on the trait being assessed. The relative accuracy of a test is represented by a reliability coefficient symbolized as r_{xx}. Since it is based on the homogeneity or consistency of the individual items of a test and no outside criteria or information are necessary for its calculation, r_{xx} is frequently referred to as internal consistency reliability or as an estimate of item homogeneity. Error caused by domain sampling is also sometimes estimated by determining the correlation between two parallel forms of a test (forms of a test that are designed to measure the same variable with items sampled from the same item domain and believed to be equivalent). The correlation between the two equivalent or alternate forms is then taken as the reliability estimate and is usually symbolized as r_{xx}, r_{ab}, or r_{xy} (although r_{xy} is generally used to represent a validity coefficient).

Split-half reliability estimates can also be determined on any specific test as a measure of internal consistency. Split-half reliability is typically determined by correlating each person's score on the one-half of the items with his or her score on the other half of the test with a correction for the original length of the test, since length will affect reliability. Predetermined or planned split-half comparisons such as correlating scores on odd numbered items with scores on the even numbered items may take advantage of chance or other factors resulting in spuriously high estimates of reliability. A reliability coefficient called alpha is a better method for estimating reliability since it is the mean of all possible split-half comparisons, thus expunging any sampling error resulting from the method of dividing the test for the purposes of calculating a correlation between each half.

As noted earlier, a number of techniques exist for estimating reliability. Throughout this chapter, reliability has been referred to as estimated. This is because the absolute or "true" reliability of a psychological test can never be determined. Alpha and all other methods of determining reliability are, however, considered to be lower bound estimates of the true reliability of the test. One can be certain that the reliability of a test is at least as high as the calculated estimate and possibly even higher.

Once the reliability of a test has been estimated, it is possible to calculate a sometimes more useful statistic known as the standard error of measurement. Since there is always some error involved in the score a person obtains on a psychological test, the obtained score (X_i) does not truly represent the individual's standing with regard to the trait in question. Obtained scores estimate an individual's true score on the test (the score that would be obtained if there was no error involved in the measurement). Since this is not possible, the true score (X_∞) is defined as the mean score of an individual if administered an infinite number of equivalent forms of a test and there were no practice effects or other intervening factors. The standard error of measurement (S_{em}) is the SD of the individual's distribution of scores about his or her true score. To determine the S_{em} it is necessary to know only the SD and the reliability (preferably an internal consistency estimate) of the test in question. The calculation of X_∞ and S_{em} are only estimates, however, since the conditions for determining a true score never actually exist.

Since the distribution of obtained scores about the true score is considered to be normal, one can establish a degree of confidence in test results by banding the estimated true score by a specified number of S_{em}s. A table of values associated with the normal curve (pictured in Figure 1) quickly tells us how many S_{em}s are necessary for a given level of confidence. In a normal distribution, about 68% of all scores fall within 1 SD of the mean, and about 95% of all scores fall within 2 SDs of the mean. Therefore, if one wanted to be 68% certain that a range of scores contained a person's true score, X_∞ would be banded by $\pm 1\ S_{em}$. To be 95% certain that a range of scores contained the true score, a range of $X_\infty \pm 2\ S_{em}$s would be necessary.

When evaluating a test or performance on a test, it is important to ascertain just what type of reliability estimate is being reported. S_{em}s should typically be calculated from an internal consistency estimate. Comparisons of reliability estimates across tests should be based on the same type of estimate. For example, one should not compare the reliability of two tests based on alternate form correlations for one test and estimation of the alpha coefficient for the other.

Test–retest correlations, also frequently referred to as reliability coefficients, should not be confused with measures of the accuracy or precision of a test at a given point in time.

Test–retest "reliability" is one of the most often confused concepts of psychometric theory. Even Anastasi (1976), in introducing reliability, refers to reliability as a measure of the degree to which a person would obtain the same score if tested again at a later time. In the earlier stages of development of psychology when traits were considered unchanging, test–retest reliability was properly considered to be a characteristic of the test and indeed was believed to be an indication of the degree to which a person would obtain the same score if tested again. Test–retest reliability speaks principally of the stability of the trait being measured and has little to do with the accuracy or precision of measurement unless the psychological construct in question is considered to be totally unchangeable. Given that traits such as anxiety and even intelligence do in fact change over time and that testing from one time to the next is positively correlated, it is still possible to use the test–retest correlation to determine estimates of what score a person would obtain upon retesting. Internal consistency estimates, however, should not be interpreted in such a manner. When psychological constructs are not highly labile and believed to change only over long periods of time, test–retest correlations may be considered to reflect the accuracy of a test if the two testings occur at close points in time during which the trait under consideration is believed to be stable.

4.02.4.2 Generalizability Theory

Generalizability theory is an extension of true score theory (also known as classical test theory) that is achieved principally through use of analysis of variance (ANOVA) procedures. Often, more than one type of error is acting on a reliability coefficient. For example, in true score theory, errors due to domain sampling (e.g., not asking about every possible symptom of depression), errors due to faulty administration, scoring errors by the examiner, and errors associated with time sampling may all act to lower the average interitem correlation, which will reduce the internal consistency reliability of the test score. Under true score theory, it is impossible to partial the relative contributions, that is, to determine how much error is contributed by each subset of error to the total amount of unreliability. Even test–retest or stability coefficients are confounded by internal consisting errors. The maximum r_{12} is equal to the square root of r_{xx} or max $r^{12} = (r_{xx})^{1/2}$.

Generalizability theory takes advantage of the capabilities of ANOVA in partitioning variance components to develop a model of unreliability (as opposed to concentrating on statistical significance). Through ANOVA, generalizability theory is able to partition the error variance of a set of scores into the components listed above, such as domain sampling error and the like, along with some additional components not considered in true score theory. Generalizability theory is no more difficult mathematically than true score theory. Generalizability theory is surprisingly absent from the measurement repertoire of most clinicians but is becoming increasingly popular among measurement scientists. However, the understanding and application of generalizability theory does require an understanding of methods and designs for partitioning variance components in ANOVA, a skill that is perhaps on the decline in clinical training programs in favor of statistical methods more aligned with structural equation modeling.

The basic foundations of generalizability theory can be found in Cronbach, Rajaratnam, and Gleser (1963). A current, detailed explanation appears in Feldt and Brennan (1989) along with the necessary mathematical models necessary to apply generalizability theory to the concept of error in test scores of groups and individuals.

4.02.5 VALIDITY

Reliability refers to the precision or accuracy of test scores. Validity refers to the appropriateness of the interpretations of test scores and not to the test or the score itself. "Validity is an integrated evaluative judgment of the degree to which empirical evidence and theoretical rationales support the adequacy and the appropriateness of inferences and actions based on test scores or other modes of assessment" (Messick, 1989, p. 13). As is reliability, validity is a matter of degree and not an all or none concept. Reliability will, however, enter into evaluation of the validity of an inference drawn from a test score. Reliability is a necessary but insufficient condition for validity. As reliability approaches zero, the amount of random error in a test score increases. The greater the relative proportion of random error present, the less confidence one can have in any interpretation of a score since, by definition, random error is unrelated to anything meaningful. Validation is not static but is an ongoing process, not just of the corroboration of a particular meaning, but for the development of sounder and better interpretations of observations that are expressed as scores on a psychological test.

Although it is often done as a matter of convenience or as simple short hand, it should be obvious by now that it is not correct technically to refer to the validity of a test. Validity is a characteristic of the interpretation given to performance on a test. It makes no sense, for example, to ask a question such as "Is this Wechsler scale a valid test?" Rather, one might pose the superior question "Is the interpretation of performance on this Wechsler scale as reflecting intelligence or intellectual level valid?" This is more than a game of semantics as such subtle differences in language affect the way we think about our methods and our devices. The difference in language and its implications are considered powerful enough that *Educational and Psychological Measurement*, one of the oldest and most respected journals in psychometrics, founded originally by Frederic Kuder, no longer allows authors in its pages to refer to the validity of a test or the reliability of a test. Reviewers for this journal are asked routinely to screen manuscripts for improper or imprecise use of such terminology.

Just as reliability may take on a number of variations, so may validity. Quite a bit of divergent nomenclature has been applied to validity. Messick (1980) identified 17 "different" types of validity that are referred to in the technical literature! Traditionally, validity has been broken into three major categories: content, construct, and predictive or criterion-related validity. These are the three types of validity distinguished and discussed in the joint *Standards for Educational and Psychological Tests* (American Psychological Association, 1985). Construct validity cuts across all categories, and criterion-related validity is definitely a question of the relationship of test performance to other methods of evaluating behavior.

Content validity is determined by how well the test items and their specific content sample the set of behaviors or subject matter area about which inferences are to be drawn on the basis of the test scores. Criterion-related or predictive validity refers to either comparisons of test scores with performance on accepted criteria of the construct in question taken in close temporal relationship to the test or the level of prediction of performance at some future time. Criterion-related validity is determined by the degree of correspondence between the test score and the individual's performance on the criterion. If the correlation between these two variables is high, no further evidence may be considered necessary (Nunnally, 1978). Here, reliability has a direct, and known, limiting effect on validity. A correlation between a predictor (x) and a criterion (y), a validity coefficient, typically expressed as r_{xy}, is restricted in magnitude. Its maximum true value is equal to the square root of the product of the internal consistency reliability coefficients of the scores being compared: $r_{xy}\ \max = (r_{xx}\, r_{yy})^{1/2}$.

Construct validity of the interpretations given to psychological tests is one of the most complex issues facing the psychometrician and permeates all aspects of test development and test use. Psychology for the most part deals with intangible constructs. Intelligence is one of the most intensely studied constructs in the field of psychology, yet it cannot be directly observed or evaluated. Intelligence can only be inferred from the observation and quantification of what has been agreed upon as "intelligent" behavior. Personality variables such as dependence, anxiety, need achievement, mania, and on through the seemingly endless list of personality traits that psychologists have "identified" also cannot be observed directly. Their existence is only inferred from the observation of behavior. Construct validity thus involves considerable inference on the part of the test developer and the researcher; construct validity is evaluated by investigating just what psychological properties a test measures.

Prior to being used for other than research purposes, interpretations given to a test must be shown clearly to demonstrate an acceptable level of validity. For use with various categories of psychopathology, validation with normally functioning individuals should be considered insufficient. The validity of an interpretation needs to be demonstrated for each group with whom it is used. This can be a long and laborious process but is nevertheless a necessary one. There are many subtle characteristics of various classes of exceptional children, for example, that may cause an otherwise appropriate interpretation of a test to lack validity with special groups (e.g., see Newland, 1980).

As has been noted by Cronbach (1971) and others, the term "test validation" can cause some confusion. In thinking about and evaluating validity, we must always keep in mind that one does not ever actually validate a test but only the interpretation that is given to the score on the test. Any test may have many applications and a test with originally a singular purpose may prove promising for other applications. Each application of a test or interpretation of a test score must undergo validation. Whenever hearing or reading that a test has been validated, we need to know for what purpose it has been validated, and what interpretations of scores from the instrument in question have been shown empirically to be justifiable and accurate.

4.02.6 THE ASSESSMENT PROCESS

As noted at the opening of this chapter, assessment is an involved, comprehensive process of deriving meaning from test scores to achieve a broad but detailed description and understanding of the individual. The description here of assessment as a process is important. Assessment, properly carried out, is not a static collection of information, but an ongoing dynamic synthesis and evaluation of data, reliably obtained, from multiple sources relevant to the current, and possibly future, status of the individual. Assessment is open ended—new information can occur daily that can properly alter one's perception of the ecological validity of prior impressions and recommendations.

Crucial to the assessment process, and far too frequently neglected or overlooked, is follow-up evaluation that should occur after more formal diagnostic assessments have been made and habilitative recommendations implemented. There are no absolutes in psychological and educational testing; no profile of assessment information is inexorably linked with a single method of treatment, remediation, or intervention that will always be successful. Currently, the opposite is the case; the search for the aptitude × treatment interaction is nearly as elusive as that for the neural engram. The follow-up component of the assessment process is crucial to the fine-tuning of existing intervention procedures and in some cases more massive overhauling of an intervention.

Psychological and educational testing and assessment are far from exact, just as are the clinical assessment procedures of medicine and related specialties. When used in diagnosis, assessment allows one simply to narrow the number of disorders under serious consideration. Similarly, when used in the search for an appropriate method of habilitation for a handicapped youngster, the assessment process allows the psychologist to narrow the number of strategies (i.e., hypotheses) from which to choose one that is believed to be most effective. There are no guarantees that the first strategy adopted will be the most effective program of treatment (or be effective at all for that matter). Kaufman (1994) described the proper attitude of the psychologist involved in assessment to be that of a "detective" who evaluates, synthesizes, and integrates data gleaned from the assessment process with knowledge of psychological theories of development and the psychology of individual differences (also see Reynolds, 1981b; Reynolds & Clark, 1982). As described here, the assessment process is a major component in psychological problem-solving. Individuals are not randomly selected for an expensive, time-consuming psychological evaluation. They are referred to a psychologist for some more or less specific reason; a problem of some kind exists. The assessment process then plays a major role in accurately identifying and describing the problem, suggesting solutions, and properly carried through, provides ideas for modifying the initially proposed interventions.

It is necessary in the assessment process to entertain and evaluate information from a variety of sources if the assessment is to be ecologically valid. Each situation will dictate the relevance and appropriate weighting of each piece of information. Age and physical condition are two obvious factors that influence the gathering of information regarding child and adult patients. Palmer (1980), Newland (1980), Salvia and Ysseldyke (1981), and Sattler (1988) have discussed factors to be included in the assessment process when evaluating exceptional children in the schools. The following are generally accepted to be important aspects of assessment: medical condition, sensory and motor skills, school performance and behavior (e.g., group achievement tests, grades, teacher checklists), individual intelligence test scores, special aptitude and achievement test performance, affective characteristics (e.g., personality tests), teacher reports on behavior and peer interaction, the child–school interaction, characteristics of the classroom, parent reports on behavior, the social and cultural milieu of the home, and the child's developmental history. Each of these factors takes on more or less importance for individual patients. With adult patients, many of the same types of information will be relevant with a conceptual shift toward adulthood (Anastasi & Urbina, 1997). The patient's vocational functioning and relationships including parents, spouse, and children will all need to be considered when designing the assessment and later when interpreting the results. More specialized types of knowledge may be required for any given case. For example, in certain genetically-based disorders, a complete family history may be necessary to achieve a good understanding of the nature of the patient's difficulty.

Numerous methods of psychological testing can be used in the assessment process. Each will have its own strengths and weaknesses. There are frequent debates in the psychological literature over the relative merits of one category of assessment over another, with some respondents carrying on with nearly religious fervor. However, these arguments can be resolved quickly by recalling that tests are tools of assessment and most certainly not an end in themselves. Different methods and techniques of testing are best seen and used as complementary in assessment, which is a problem-solving process requiring much information. With these admonitions in mind, it is time to turn to a discussion of various methods of testing and their role in the assessment process.

4.02.7 MODELS AND METHODS OF ASSESSMENT

A variety of assessment methods are available for evaluating adults and exceptional children. Some of these methods grew directly from specific schools of psychological thought, such as the psychoanalytic view of Freud (projective assessment techniques) or the behavioral schools of Watson, Skinner, and Bandura (applied behavior analysis). Other methods have grown out of controversies in and between existing academic disciplines such as personality theory and social psychology. New and refined methods have come about with new developments in medicine and related fields, whereas other new testing methods stem from advances in the theory and technology of the science of psychological measurement. Unfortunately, still other new techniques stem from psychological and educational faddism with little basis in psychological theory and little if any empirical basis. Any attempt to group tests by characteristics such as norm-referenced vs. criterion-referenced, traditional vs. behavioral, maximum vs. typical performance, and so on, is doomed to criticism. As will be seen in the pages that follow, the demarcations between assessment methods and models are not so clear as many would contend. In many cases, the greatest distinctions lie in the philosophical orientation and intent of the user. As one prominent example, many "behavioral" assessment techniques are as bound by norms and other traditional psychometric concepts as are traditional intelligence tests (Cone, 1977). Even trait measures of personality end up being labeled by some as behavioral assessment devices (e.g., Barrios, Hartmann, & Shigetomi, 1981). The division of models and methods of assessment to follow is based in some part on convenience and clarity of discussions but also with an eye toward maintaining the most important conceptual distinctions among these assessment methods.

4.02.7.1 Traditional Norm-referenced Assessment

4.02.7.1.1 Intelligence, achievement, and special abilities

These assessment techniques have been grouped together primarily because of their similarity of content and, in some cases, their similarity of purpose. There are, however, some basic distinctions among these measures. Intelligence tests tend to be broad in terms of content; items sample a variety of behaviors that are considered to intellectual in nature. Intelligence tests are used both to evaluate the current intellectual status of the individual and to predict future behavior on intellectually demanding tasks and to help achieve a better understanding of past behavior and performance in an intellectual setting. Achievement tests measure relatively narrowly defined *content*, sampled from a specific subject matter domain that typically has been the focus of purposeful study and learning by the population for whom the test is intended. Intelligence tests by contrast are oriented more toward testing intellectual processes and use items that are more related to incidental learning and not as likely to have been specifically studied as are achievement test items. Tests of special abilities, such as memory, mechanical aptitude, and auditory perception, are narrow in scope as are achievement tests but focus on process rather than content. The same test question may appear on an intelligence, achievement, or special ability test, however, and closely related questions frequently do. Tests of intelligence and special abilities also focus more on the application of previously acquired knowledge, whereas achievement tests focus on testing just what knowledge has been acquired. One should not focus on single items; it is the collection of items and the use and evaluation of the individual's score on the test that are the differentiating factors.

(i) Intelligence tests

Intelligence tests are among the oldest devices in the psychometric arsenal of the psychologist and are likely the most frequently used category of tests in the evaluation of exceptional children, especially in the cases of mental retardation, learning disabilities, and intellectual giftedness. Intelligence and aptitude tests are used frequently in adult assessment as well and are essential diagnostic tools when examining for the various dementias. They are used with adults in predicting a variety of other cognitive disorders and in the vocational arena. Since the translation and modification of Alfred Binet's intelligence test for French schoolchildren was introduced in the United States by Lewis Terman (of Stanford University, hence the Stanford–Binet Intelligence Scale), a substantial proliferation of such tests has occurred. Many of these tests measure very limited aspects of intelligence (e.g., Peabody Picture Vocabulary Test, Columbia Mental Maturity Scale, Ammons and Ammons Quick Test), whereas others give a much broader view of a person's intellectual skills, measuring general intelligence as well as more specific cognitive skills (e.g., the various Wechsler scales). Unfortunately, while intelligence is a hypothetical psychological construct, most intelligence tests were developed from a primarily empirical basis, with little if any attention given to theories of the human intellect. Empiricism is of major importance in all aspects of psychology, especially psychological testing, but is insufficient in itself. It is important to have a good theory underlying the assessment of any theoretical construct such as intelligence.

Intelligence tests in use today are for the most part individually administered (i.e., a psychologist administers the test to an individual in a closed setting with no other individuals present). For a long time, group intelligence tests were used throughout the public schools and in the military. Group tests of intelligence are used more sparingly today because of their many abuses in the past and the limited amount of information they offer about the individual. There is little of utility to the schools, for example, that can be gleaned from a group intelligence test that cannot be obtained better from group achievement tests. Individual intelligence tests are far more expensive to use but offer considerably more and better information. Much of the additional information, however, comes from having a highly trained observer (the psychologist) interacting with the person for more than an hour in a quite structured setting, with a variety of tasks of varying levels of difficulty. The most widely used individually administered intelligence scales today are the Wechsler scales, the Kaufman scales, and the Stanford–Binet Intelligence Scale (Fourth Edition). Though the oldest and best known of intelligence tests, the Binet has lost much of its popularity and is now a distant third.

Intelligence testing, which can be very useful in clinical and vocational settings, is also a controversial activity, especially with regard to the diagnosis of mild mental retardation among minority cultures in the United States. Used with care and compassion, as a tool toward understanding, such tests can prove invaluable. Used recklessly and with rigidity, they can cause irreparable harm. Extensive technical training is required to master properly the administration of an individual intelligence test (or any individual test for that matter). Even greater sensitivity and training are required to interpret these powerful and controversial devices. Extensive knowledge of statistics, measurement theory, and the existing research literature concerning testing is a prerequisite to using intelligence tests. To use them well requires mastery of the broader field of psychology, especially differential psychology, the psychological science that focuses on the psychological study and analysis of human individual differences and theories of cognitive development. Extensive discussions of the clinical evaluation of intelligence can be found in Kaufman (1990, 1994) and Kaufman and Reynolds (1983).

(ii) Achievement tests

Various types of achievement tests are used throughout the public schools with regular classroom and exceptional children. Most achievement tests are group tests administered with some regularity to all students in a school or system. Some of the more prominent group tests include the Iowa Test of Basic Skills, the Metropolitan Achievement Test, the Stanford Achievement Test, and the California Achievement Test. These batteries of achievement tests typically do not report an overall index of achievement but rather report separately on achievement in such academic areas as English grammar and punctuation, spelling, map reading, mathematical calculations, reading comprehension, social studies, and general science. The tests change every few grade levels to accommodate changes in curriculum emphasis. Group achievement tests provide schools with information concerning how their children are achieving in these various subject areas relative to other school systems throughout the country and relative to other schools in the same district. They also provide information about the progress of individual children and can serve as good screening measures in attempting to identify children at the upper and lower ends of the achievement continuum. Group administered achievement tests help in achieving a good understanding of the academic performance of these individuals but do not provide sufficiently detailed or sensitive information on which to base major decisions. When decision-making is called for or an in-depth understanding of a child's academic needs is required, individual testing is needed.

Psychologists use achievement measures with adult clients as well. With the elderly, acquired academic skills tend to be well preserved in the early stages of most dementias and provide a good baseline of promorbid skills. Academic skills can also be important in recommending job placements, as a component of child custody evaluations, in rehabilitation planning, and in the diagnosis of adult learning disorders and adult forms of attention deficit hyperactivity disorder.

(iii) Tests of special abilities

These are specialized methods for assessing thin slices of the spectrum of abilities for any single individual. These measures can be helpful in further narrowing the field of hypotheses about an individual's learning or behavior difficulties when used in conjunction with intelligence, achievement, and personality measures. The number of special abilities that can be assessed is quite large. Some examples of these abilities include visual–motor integration skills, auditory perception, visual closure, figure–ground distinction, oral expression, tactile form recognition, and psychomotor speed. While these measures can be useful, depending on the questions to be answered, one must be particularly careful in choosing an appropriate, valid, and reliable measure of a special ability. The use and demand for these tests are significantly less than that for the most popular individual intelligence tests and widely used achievement tests. This in turn places some economic constraints on development and standardization procedures, which are very costly enterprises when properly conducted. One should always be wary of the "quick and dirty" entry into the ability testing market. There are some very good tests of special abilities available, although special caution is needed. For example, simply because an ability is named in the test title is no guarantee that the test measures that particular ability. As with all tests, what is actually measured by any collection of test items is a matter for empirical investigation and is subject to the process of validation.

To summarize, norm-referenced tests of intelligence, achievement, and special abilities provide potentially important information in the assessment process. Yet each supplies only a piece of the required data. Equally important are observations of how the patient behaves during testing and in other settings, and performance on other measures.

4.02.7.2 Norm-referenced, Objective Personality Measures

Whereas tests of aptitude and achievement can be described as maximum performance measures, tests of personality can be described as typical performance measures. When taking a personality test, one is normally asked to respond according to one's typical actions and attitudes and not in a manner that would present the "best" possible performance (i.e., most socially desirable). The "faking" or deliberate distortion of responses is certainly possible, to a greater extent on some scales than others (e.g., Jean & Reynolds, 1982; Reynolds, 1998b), and is a more significant problem with personality scales than cognitive scales. Papers have even been published providing details on how to distort responses on personality tests in the desired direction (e.g. Whyte, 1967). Although there is no direct solution to this problem, many personality measures have built-in "lie" scales or social desirability scales to help detect deliberate faking to make one look as good as possible and F or infrequency scales to detect the faking of the presence of psychopathology.

The use and interpretation of scores from objective personality scales also has implications for this problem. Properly assessed and evaluated from an empirical basis, response to the personality scale is treated as the behavior of immediate interest and the actual content conveyed by the item becomes nearly irrelevant. As one example, there is an item on the Revised-Children's Manifest Anxiety Scale (RCMAS; Reynold's & Richmond, 1978, 1985), a test designed to measure chronic anxiety levels in children, that states "My hands feel sweaty." Whether the child's hands actually do feel sweaty is irrelevant. The salient question is whether children who respond "true" to this question are in reality more anxious than children who respond "false" to such a query. Children who respond more often in the keyed direction on the RCMAS display greater general anxiety and exhibit more observed behavior problems associated with anxiety than children who respond in the opposite manner. Although face validity of a personality or other test is a desirable quality, it is not always a necessary one. It is the actuarial implications of the behavioral response of choosing to respond in a certain manner that holds the greatest interest for the practitioner. Scales developed using such an approach are empirical scales.

Another approach is to devise content scales. As the name implies, the item content of such scales is considered more salient than its purely empirical relationship to the construct. Individuals with depression, especially men, may be edgy and irritable at times. Thus, the item "I sometimes lash out at others for no good reason" might show up on an empirically derived scale assessing depression, but is unlikely to find its way onto a content scale. "I am most often sad" would be a content-scale item assessing depression. Content scales are typically derived via expert judgments, but from an item pool that has passed muster at some empirical level already.

The emphasis on inner psychological constructs typical of personality scales poses special problems for their development and validation. A reasonable treatment of these issues can be found in most basic psychological measurement texts (e.g., Anastasi & Urbina, 1997; Cronbach, 1983).

Objective personality scales are probably the most commonly used of all types of tests by clinical psychologists. They provide key evidence for the differentiation of various forms of psychopathology including clinical disorders and especially personality disorders. Omnibus scales such as the MMPI-2 and the Millon Clinical Multiaxial Inventory-3 are common with adult populations and also have adolescent versions. Omnibus scales directed at children and adolescents specifically however may be more appropriate for these younger age ranges. Among the many available, the Personality Inventory for Children and the Self-report of Personality from the Behavior Assessment System for Children (BASC: Reynolds & Kamphaus, 1992) are the most commonly used. Omnibus scales that are multidimensional in their construction are important to differential diagnosis in the early stages of contact with a patient. As diagnosis is established and treatment is in place, narrower scales that coincide with the clinical diagnosis become more useful for follow-up assessment and monitoring of treatment. In this regard, scales such as the Beck Depression Inventory or the State-Trait Anxiety Inventory are common examples. The tremendous cultural diversity of the world and how culture influences perceptions of items about the self and about one's family places special demands of cultural competence and cultural sensitivity on psychologists interpreting personality scales outside of their own cultural or ethnic heritage (e.g., see Dana, 1996; Hambleton, 1994; Moreland, 1995).

4.02.7.3 Projective Assessment

Projective assessment of personality has a long, rich, but very controversial history in the evaluation of clinical disorders and the description of normal personality. This controversy stems largely from the subjective nature of the tests used and the lack of good evidence of predictive validity coupled with sometimes fierce testimonial and anecdotal evidence of their utility in individual cases by devoted clinicians.

The subjectiveness of projective testing necessarily results in disagreement concerning the scoring and interpretation of responses to the test materials. For any given response by any given individual, competent professionals would each be likely to interpret differently the meaning and significance of the response. It is primarily the agreement on scoring that differentiates objective from subjective tests. If trained examiners agree on how a particular answer is scored, tests are considered objective; if not, they are considered subjective. Projective is not synonymous with subjective in this context but most projective tests are closer to the subjective than objective end of the continuum of agreement on scoring of responses. Projective tests are sets of ambiguous stimuli, such as ink blots or incomplete sentences, and the individual responds with the first thought or series of thoughts that come to mind or tells a story about each stimulus. Typically no restrictions are placed on individuals' response options. They may choose to respond with anything desired; in contrast, on an objective scale, individuals must choose between a set of answers provided by the test or at least listed out for the examiner in a scoring manual. The major hypothesis underlying projective testing is taken from Freud (Exner, 1976). When responding to an ambiguous stimulus, individuals are influenced by their needs, interests, and psychological organization and tend to respond in ways that reveal, to the trained observer, their motivations and true emotions, with little interference from the conscious control of the ego. Various psychodynamic theories are applied to evaluating test responses, however, and herein too lie problems of subjectivity. Depending on the theoretical orientation of the psychologist administering the test, very different interpretations may be given. Despite the controversy surrounding these tests, they remain very popular.

Projective methods can be divided roughly into three categories according to the type of stimulus presented and the method of response called for by the examiner. The first category calls for the interpretation of ambiguous visual stimuli by the patient with an oral response. Tests in this category include such well-known techniques as the Rorschach and the Thematic Apperception Test (TAT). The second category includes completion methods, whereby the patient is asked to finish a sentence when given an ambiguous stem or to complete a story begun by the examiner. This includes the Despert Fables and a number of sentence completion tests. The third category includes projective art, primarily drawing techniques, although sculpture and related art forms have been used. In these tasks, the child is provided with materials to complete an artwork (or simple drawing) and given instructions for a topic, some more specific than others. Techniques such as the Kinetic-Family-Drawing, the Draw-A-Person, and the Bender–Gestalt Test fall in this category.

Criterion-related and predictive validity have proven especially tricky for advocates of projective testing. Although techniques such as the TAT are not as amenable to study and validation through the application of traditional statistical and psychometric methods as objective tests may be, many clinical researchers have made such attempts with less than heartening results. None of the so-called objective scoring systems for projective devices has proved to be very valuable in predicting behavior, nor has the use of normative standards been especially fruitful. This should not be considered so surprising; however, it is indeed the nearly complete idiographic nature of projective techniques that can make them useful in the evaluation of a specific patient. It allows for any possible response to occur, without restriction, and can reveal many of a patient's current reasons for behaving in a specific manner. When used as part of a complete assessment, as defined in this chapter, projective techniques can be quite valuable. When applied rigidly and without proper knowledge and consideration of the patient's ecology, they can, as with other tests, be detrimental to our understanding of the patient. For a more extensive review of the debates over projective testing, the reader is referred to Exner (1976), Jackson and Messick (1967, Part 6), O'Leary and Johnson (1979), and Prevatt (in press), as well as to other chapters in this volume, especially Chapter 15.

4.02.7.4 Behavioral Assessment

The rapid growth of behavior therapy and applied behavior analysis has led to the need for tests that are consistent with the theoretical and practical requirements of these approaches to the modification of human behavior. Thus, the field of behavioral assessment has developed and grown at an intense pace. Book length treatments of the topic became commonplace in the 1970s and 1980s (e.g., Haynes & Wilson, 1979; Hersen & Bellack, 1976; Mash & Terdal, 1981) and entire journals are now devoted to research regarding behavioral assessment (e.g., *Behavioral Assessment*). The general term "behavioral assessment" has come to be used to describe a broad set of methods including some traditional objective personality scales, certain methods of interviewing, physiological response measures, naturalistic observation, norm-referenced behavior checklists, frequency counts of behavior, and a host of informal techniques requiring the observation of a behavior with recording of specific responses. Behavioral assessment will be discussed here in its more restricted sense to include the rating (by self or others) of observable behavioral events, primarily taking the form of behavior checklists and rating forms that may or may not be normed. Although I would certainly include psychophysiological assessment within this category, the scope of the work simply will not allow us to address this aspect of behavioral assessment except to say that it is indeed a most useful one in the treatment of a variety of clinical disorders.

The impetus for behavioral assessment comes not only from the field of behavior therapy but also from a general revolt against the high level of inference involved in such methods of assessing behavior as the Rorschach and the TAT. The greatest distinguishing characteristic between the behavioral assessment of psychopathological disorders and most other techniques is the level of inference involved in moving from the data provided by the assessment instrument to an accurate description of the patient and the development of an appropriate intervention strategy. This is a most useful strength for behavioral assessment strategies but is their greatest weakness when it is necessary to understand what underlies the observed behaviors.

Many of the early conceptual and methodological issues have been resolved in this area of assessment, for example, the importance of norms and other traditional psychometric concepts such as reliability and validity (Cone, 1977; Nelson, Hay, & Hay, 1977). Problems of interobserver reliability and observer drift remain but are well on their way to being resolved. Unquestionably, behavioral assessment is an exciting and valuable part of the assessment process. Behavioral assessment grew from a need to quantify observations of a patient's current behavior and its immediate antecedents and consequences, and this is the context within it that remains most useful today.

There are a number of formal behavior rating scales or behavior checklists now available. These instruments typically list behaviors of interest in clearly specified terms and have a trained observer or an informant indicate the frequency of occurrence of these behaviors. Interpretation can then take on a normative or a criterion-reference nature depending on the purpose of the assessment and the availability of norms. Clusters of behaviors may be of interest that define certain clinical syndromes such as attention deficit hyperactivity disorder. On the other hand, individual behaviors may be the focus (e.g., hitting other children). More frequently, behavioral assessment occurs as an "informal" method of collecting data on specific behaviors being exhibited by a patient and is dictated by the existing situation into which the psychologist is invited. An informal nature is dictated by the nature of behavioral assessment in many instances. Part of the low level of inference in behavioral assessment lies in not generalizing observations of behavior across settings without first collecting data in multiple settings. In this regard, behavioral assessment may for the most part be said to be psychosituational. Behavior is observed and evaluated under existing circumstances, and no attempt is made to infer that the observed behaviors will occur under other circumstances. Comprehensive systems that are multimethod, multidimensional, and that assess behavior in more than one setting have been devised and provide a good model for the future (Reynolds & Kamphaus, 1992).

Another area of assessment that stems from behavioral psychology and is considered by many to be a subset of behavioral assessment is task analysis. Whereas behavioral assessment typically finds its greatest applicability in dealing with emotional and behavioral difficulties, task analysis is most useful in evaluating and correcting learning problems. In task analysis, the task to be learned (e.g., brushing one's teeth or multiplying two-digit numbers) is broken down into its most basic component parts. The learner's skill at each component is observed and those skills specifically lacking are targeted for teaching to the child. In some cases, hierarchies of subskills can be developed, but these have not held up well under cross-validation. Task analysis can thus be a powerful tool in specifying a learner's existing (and needed) skills for a given learning problem. Task analysis could, for example, form an integral part of any behavioral intervention for a child with specific learning problems. The proper use of these procedures requires a creative and well-trained individual conversant with both assessment technology and behavioral theories of learning, since there are no standardized task analysis procedures. Those involved in task analysis need to be sensitive to the reliability and validity of their methods. As with other behavioral assessment techniques, some contend that behavioral assessment techniques need only demonstrate that multiple observers can agree on a description of the behavior and when it has been observed. Though not having to demonstrate a relationship with a hypothetical construct, behavioral techniques must demonstrate that the behavior observed is consistent and relevant to the learning problems. For behavior checklists and more formal behavioral assessment techniques, most traditional psychometric concepts apply and must be evaluated with regard to the behavioral scale in question.

4.02.7.5 Neuropsychological Assessment

Along with behavioral assessment, perhaps the most rapidly growing area in patient evaluation is neuropsychological assessment. Many view neuropsychological assessment as the application of a specific set of tests or battery of tests. Far from being a set of techniques, the major contribution of neuropsychology to the assessment process is the provision of a strong paradigm from which to view assessment data (Reynolds, 1981b, 1981c, 1997). Without a strong theoretical guide to test score interpretation, one quickly comes to rely upon past experience and illusory relationships and trial and error procedures when encountering a patient with unique test performance. As with most areas of psychology, there are competing neuropsychological models of cognitive functioning, any one of which may be most appropriate for a given patient. Thus considerable knowledge of neuropsychological theory is required to evaluate properly the results of neuropsychological testing.

Since the 1950s, clinical testing in neuropsychology has been dominated by the Halstead–Reitan Neuropsychological Test Battery (HRNTB), although the Luria–Nebraska Neuropsychological Battery and the Boston process approach have made significant inroads. The prevalence of use of the HRNTB is partly responsible for perceptions of clinical neuropsychology as primarily a set of testing techniques. However, a brief examination of the HRNTB should quickly dispel such ideas. The HRNTB consists of a large battery of tests taking a full day to administer. There is little that can be said to be psychologically or psychometrically unique about any of these tests. They are all more or less similar to tests that psychologists have been using for the past 50 years. The HRNTB also typically includes a traditional intelligence test such as one of the Wechsler scales. The HRNTB is unique in the particular collection of tests involved and the method of evaluating and interpreting performance. While supported by actuarial studies, HRNTB performance is evaluated by the clinician in light of existing neuropsychological theories of cognitive function, giving the battery considerable explanatory and predictive power.

Neuropsychological approaches to clinical assessment are rapidly growing and can be most helpful in defining areas of cognitive-neuropsychological integrity and not just in evaluating deficits in neurological function. Neuropsychological techniques can also make an important contribution by ruling out specific neurological problems and pointing toward environmental determinants of behavior. The well-trained neuropsychologist is aware that the brain does not operate in a vacuum but is an integral part of the ecosystem of the patient. As with other methods of assessment, neuropsychological assessment has much to offer the assessment process when used wisely; poorly or carelessly implemented, it can create seriously false impressions, lessen expectations, and precipitate a disastrous state of affairs for the patient it is designed to serve. Clinicians who use neuropsychological approaches to their work or make neuropsychological interpretations of tests or behaviors are in high demand but require specialized training that takes years to acquire.

4.02.8 CLINICAL VS. STATISTICAL PREDICTION

Given a set of test results and/or additional interview or historical data on a patient, there are two fundamental approaches a clinician can apply to diagnostic decision-making or to the prediction of future behavior. The first, and likely most common, is the simple human judgment of the clinician who reviews the data in conjunction with prior experiences and knowledge of diagnostic criteria, psychopathology, and other psychological literature. As a result of the application of this *clinical method*, a diagnosis or prediction is made. Alternatively, the clinician may apply a formal algorithm or set of mathematical equations to predict membership in a class (a diagnosis) or the probability of some future behavior (e.g., whether a defendant will or will not molest children again if placed on probation). The use of such mechanistic approaches constitutes the *statistical method.*

The ability of clinicians to use test data in optimal ways and to combine multiple sources of data optimally to arrive at correct diagnoses and to make predictions about future behavior has been the subject of much scrutiny. Meehl (1954) addressed this problem early on and concluded that formula-based techniques, derived by mathematical models that search for optimal combinations of data, are superior to clinicians in decision-making. This has been difficult for clinicians to accept even as more and more actuarial systems for test interpretation find their way into our office computers. In 70+ years of research on this topic, actuarial modeling continues to be superior (Faust & Ackley, 1998; Grove & Meehl, 1996), yet I listened to a clinical psychologist testify in February of 1998 that clinical judgment was always better and that actuarial predictions were used only when you had nothing else to use. In 136 studies since 1928, over a wide range of predictions, actuarial modeling is invariably equal to or superior to clinical methods (Grove & Meehl, 1996). Grove and Meehl (1996) have addressed this reluctance (or perhaps ignorance) about actuarial modeling in clinical-decision-making and clinicians' objections to acceptance of more than 70 years of consistent research findings, as has Kleinmuntz (1990), who did seminal research on developing expert systems for MMPI interpretation in the 1960s.

Grove and Meehl (1996) state the most common objection of clinicians to statistical modeling is that they (the clinicians) use a combination of clinical and statistical methods, obviating the issue since they are used in a complementary model. This is a spurious argument because, as research shows, the clinical method and the statistical method often disagree and there is no known way to combine the two methods to improve predictions; we simply do not know under what conditions to conclude the statistical model will be wrong (also see Faust & Ackley, 1998, and Reynolds, 1998a). Grove and Meehl (1996) illustrate this quandary by examining the actions of an admissions committee. Suppose the applicant's test scores, grade point average, and rank in class predict successful college performance but the admissions commission believes, perhaps based on an interview and letters of recommendation, that the applicant will not be successful. The two methods cannot be combined when they specify different outcomes. One is right and one is wrong. Consider a crucial prediction in a forensic case. A psychologist treating an offender on parole for aggravated sexual assault of a child is asked whether the offender might molest a child of the same age and gender as a prior victim if the child is placed in the offender's home (he recently married the child's mother). Actuarial tables with rearrest rates for offenders with many similar salient characteristics and in treatment indicate that 10–11% of those individuals will be arrested again for the same offense. The psychologist concludes that the offender is virtually a zero percent risk, however, because "he has worked so hard in treatment." The two methods again cannot be resolved; yet, as clinicians we persist in believing we can do better than the statistical models even in the face of a substantial body of contradictory evidence. Grove and Meehl (1996) review some 16 other objections clinicians make to statistical methods in diagnosis and other clinical predictions. Most resolve to questions of validity, reliability, or cost. Cost and inconveniences are rapidly becoming a nonissue as computerized models are widely available and some of these cost less than one dollar per application for a patient (e.g., Stanton, Reynolds, & Kamphaus, 1993).

Statistical models work better, consistently, and for known reasons. Clinicians cannot assign optimal weights to variables they use to make decisions, do not apply their own rules consistently, and are influenced by relatively unreliable data (e.g., see Dawes, 1988; Faust, 1984; Grove & Meehl, 1996; Meehl, 1954). As the reliability of a predictor goes down, the relative accuracy of any prediction will be reduced and, consequently, the probability of being wrong increases. The decisions being made are not trivial. Every day, thousands of diagnostic decisions are being made that influence treatment choices, freedom for parolees and probationers, large monetary awards in personal injury cases, custody of children, and others. What clinical psychologists do is important and the increased use of statistical models based on sound principles of data collection that includes data from well-standardized, objective psychological tests seems imperative from an ethical standpoint and from the standpoint of the survival of the profession as accountability models are increasingly applied to reviews of the need for and effectiveness of our services.

4.02.9 ACCESSING CRITICAL COMMENTARY ON STANDARDIZED PSYCHOLOGICAL TESTS

Not every practitioner can nor should be an expert on the technical adequacy and measurement science underlying each and every standardized test that might be useful to their clinical practice. With a clear understanding of the fundamentals of measurement, however, clinicians can make intelligent choices about test selection and test use based on the test manuals and accompanying materials in most cases. However, when additional expertise or commentary is required, critical reviews of nearly every published test can be accessed with relative ease.

Many journals in psychology routinely publish reviews of new or newly revised tests including such publications as the *Archives of Clinical Neuropsychology, Journal of Psychoeducational Assessment, Journal of Learning Disabilities, Journal of School Psychology, Child Assessment News,* and the *Journal of Personality Assessment*. However, the premier source of critical information on published tests are the publications of the Buros Institute of Mental Measurement.

In the late 1920s, Oscar Krisen Buros began to publish a series of monographs reviewing statistics texts. He noted the rapid proliferation of psychological and educational tests beginning to occur at the same time and rapidly turned his attention to obtaining high-quality reviews of these tests and publishing them in bound volumes known as the *Mental Measurements Yearbook* (MMY). The first MMY was published by Buros in 1938 and the series continues today. Buros died in 1978, during the final stages of production of the Eighth MMY (though "Yearbooks," they are not published annually), and his spouse, art director, and assistant Luella Buros saw the Eighth MMY to completion. Subsequently, she opened a competition for proposals to adopt the Institute and continue the work of her late husband. A proposal written by this author (then on the faculty of the University of Nebraska-Lincoln) was chosen and the Buros Institute of Mental Measurement was established in 1979 at the University of Nebraska-Lincoln, where it remains permanently due to a generous endowment from Luella Buros.

The Institute continues to seek out competent reviewers to evaluate and provide critical commentary on all educational and psychological tests published in the English language. These reviews are collected in an ongoing process, as tests are published or revised, under a strict set of rules designed to ensure fair reviews and avoid conflicts of interest. The collected reviews are published on an unscheduled basis approximately every five to eight years. However, as reviews are written and accepted for publication, they are added quickly to the Buros Institute database which may be searched on-line by subscription to the master database or through most major university libraries. Information on how to access current reviews in the Buros database can be obtained through nearly any reference librarian or through a visit to the Buros Institute website. The Institute established a sterling reputation as the "consumer reports" of the psychological testing industry under the 50 year leadership of Oscar Buros and this reputation and service have been continued at the University of Nebraska-Lincoln. Consumers of tests are encouraged to read the Buros reviews of the tests they choose to use.

4.02.10 CONCLUDING REMARKS

Knowledge of measurement science and psychometrics is critical to good practice in clinical assessment. Hopefully, this review, targeted at practice, has provided a better foundation for reading about psychological testing and for developing better skills in the application of methods of testing and assessment. Old tests continue to be revised and updated, and many new tests are published yearly. There is a large, rapidly growing body of literature on test interpretation that is too often ignored in practice (e.g., Reynolds & Whitaker, in press) but must be accessed in practice. It is difficult but necessary to do so. Measurement science also progresses and practitioners are encouraged to revisit their mathematical backgrounds every few years as part of what has become a nearly universal requirement for continuing education to continue in practice. New paradigms will always emerge as they have in the past.

It is from basic psychological research into the nature of human information processing and behavior that advances in psychological assessment must come. While some of these advances will be technological, the more fruitful area for movement is in the development of new paradigms of test interpretations. With each advance, with each "new" test that appears, we must proceed with caution and guard against jumping on an insufficiently researched bandwagon. Fruitful techniques may be lost if implemented too soon to be fully understood and appreciated; patients may also be harmed by the careless or impulsive use of assessment materials that are poorly designed (but attractively packaged) or without the necessary theoretical and empirical grounding. When evaluating new psychological assessment methods, surely *caveat emptor* must serve as the guard over our enthusiasm and our eagerness to provide helpful information about patients in the design of successful intervention programs.

4.03.1 INTRODUCTION

> To all the People and Inhabitants of the United States and all the outlying Countries, Greetings: I, John Michler, King of Tuskaroras, and of all the Islands of the Sea, and of the Mountains and Valleys and Deserts; Emperor of the Diamond Caverns, and Lord High General of the Armies thereof; First Archduke of the Beautiful Isles of the Emerald Sea; Lord High Priest of the Grand Lama, etc., etc., etc.: Do issue this my proclamation. Stand by and hear, for the Lord High Shepherd speaks. No sheep have I to lead me around, no man have I to till me the ground, but the sweet little cottage is all of my store, and my neat little cottage has ground for the floor. No children have I to play me around, no dog have I to bark me around, but the three-legged stool is the chief of my store, and my neat little cottage has ground for the floor. Yea, verily, I am the Mighty King, Lord Archduke, Pope, and Grand Sanhedrim, John Michler. None with me compare, none fit to comb my hair, but the three-legged stool is the chief of my store, and my neat little cottage has ground for the floor. John Michler is my name. Selah!
> I am the Great Hell-Bending Rip-Roaring Chief of the Aborigines! Hear me and obey! My breath overthrows mountains; my mighty arms crush the everlasting forests into kindling wood; I am the owner of the Ebony Plantations; I am the owner of all the mahogany groves and of all the satin-wood; I am the owner of all the granite; I am the owner of all the marble; I am the owner of all the owners of Everything. Hear me and obey! I, John Michler, stand forth in the presence of the Sun and of all the Lord Suns and Lord Planets of the Universe, and I say, Hear me and obey! I, John Michler, on this eighteenth day of August, 1881, do say, Hear me and obey! for with me none can equal, no, not one, for the three-legged stool is the chief of my store,

> and my neat little cottage has ground for the floor. Hear me and obey! Hear me and obey! John Michler is my name.
> John Michler, First Consul and Dictator of the World, Emperor, Pope, King and Lord High Admiral, Grand Liconthropon forever! (Hammond, 1883, pp. 603–604)

A physician in private practice in New York City reported that a man brought his brother, John Michler, to see him. John was acting strangely, and his brother wanted to know what to do. The brother gave the physician a proclamation that John Michler had written (see above). Clearly, to most observers, there would be no question that John Michler was "crazy." However, what is the diagnosis of John Michler?

When this proclamation was shown to mental health professionals, the most common diagnostic possibilities that are mentioned are schizophrenia and bipolar disorder (manic episode). What do these various diagnoses mean? Why did clinicians not assign a diagnosis of narcissistic personality disorder to this patient? Certainly this man would fit the vernacular meaning of self-centered and self-aggrandizing that is often associated with a narcissistic personality. How is a manic episode differentiated from schizophrenia? What does it mean to say that Michler appears to be psychotic? Does that diagnosis mean that he has some type of disease that has affected part of his brain, or does it suggest that his childhood was so unusual and abnormal that he has developed a strange and unusual way of coping with life?

4.03.2 PURPOSES OF CLASSIFICATION

The vernacular word that was used to describe John Michler was "crazy." This word is frequently used in descriptions of persons who have mental disorders. The reason for the applicability of this word is that one common feature of most psychiatric patients is that their behaviors are statistically abnormal. That is, psychiatric patients behave in ways that are deviant. Their interpersonal actions are not expected within the cultural context of our society.

Classification is a fundamental human activity that people use to understand their world. For instance, a classification of animals is helpful when understanding the variations among diverse forms of living organisms. In forming a classification, the classifier is attempting to use observed similarities and differences among the things being classified, so as to find some order among those things. In psychopathology, the general goal of classification is an attempt to use similarities and differences among people who behave in deviant and socially abnormal ways in order to understand their behaviors.

More specifically, there are five purposes to the classification of mental disorders: (i) forming a nomenclature so that mental health professionals have a common language; (ii) serving as a basis of information retrieval; (iii) providing a short-hand description of the clinical picture of the patient; (iv) stimulating useful predictions about what treatment approach will be best; and (v) serving as a concept formation system for a theory (or theories) of psychopathology.

The first reason to have a classification system, providing a nomenclature, is the most fundamental (World Health Organization, 1957). At a minimum, a classification system provides a set of nouns for clinicians to use to discuss their objects of interest—people. Thus, a nomenclature is a set of terms that refer to groups of people that mental health professionals see in their various professional roles.

The second reason, information retrieval, has a pragmatic focus on how well a classification organizes a research literature, so that clinicians and scientists can search for information that they need (Feinstein, 1967). In biology, there is a dictum: "the name of a plant is the key to its literature" (Sneath & Sokal, 1973). The same is true in the area of mental disorders. If a student clinician is assigned a patient who attempts to control weight by inducing vomiting, the name bulimia becomes important for helping the student locate the literature about this disorder in books, journal articles, and even on the internet.

The third reason for having a classification is description. There are many ways of creating classifications that could satisfy the first two purposes. For instance, clinicians could decide to classify all of their patients on eye color. Using eye color would allow clinicians to have a language to discuss patients ("I have seen 17 brown eyed, eight blue eyed, and four mixed eye color patients in the last month."). Also, eye color categories could be used as names to store information about patients. However, using eye color to classify patients would not be a satisfactory solution to either researchers or clinicians because patients with similar eye colors are unlikely to have similar symptom patterns. To meet the purpose of description, patients are grouped on the basis of similarity. Patients who have the same diagnosis are expected to be relatively similar in terms of symptoms (Lorr, 1966). In addition, these patients should be dissimilar when compared to patients with different diagnoses (Everitt, 1974). In the case of John Michler, if he is having a manic episode of a bipolar disorder, then we would expect that Michler's brother would report that John had been spending large sums of money that he did not have, that his speech was extremely rapid, and that his sleep pattern was markedly disturbed. In contrast, his brother is unlikely to report that Michler usually sat around the house with an emotionless, cold, detached interpersonal style and that he would tell his brother about voices in his head that were in discussion about Michler's behaviors. The latter symptoms typically occur in individuals with schizophrenia. Thus, diagnoses become descriptive short-hand names for clusters of co-occurring symptoms.

The fourth purpose is prediction. This purpose typically involves two types of inferences: (i) predicting the course of the patient's condition if there is no treatment or intervention ("Diagnosis is prognosis" as stated by Woodruff, Goodwin, & Guze, 1974); and (ii) predicting which treatment approach will be most effective with the patient (Roth & Fonagy, 1996). In the field of psychopathology, prediction has proved to be an elusive goal. Recently, there was an important multisite study that was performed in the USA in which three different treatment approaches to alcoholism were compared. An attempt was made to see whether particular groups of patients improved with specific treatments. The initial results have been negative. Except for differences related to the severity of patient symptomatology, other patient characteristics did not predict which treatments were most effective (Project Match Research Group, 1997).

The final goal of a classification is concept formation (Hempel, 1965). This goal is probably the most distant. In biological classification, Linneaus and his contemporaries made noteable gains in the classification of living organisms by creating classifications that served to describe most of the known information about these organisms. Almost a century later, Darwin formulated a theory of evolution which explained many of the organizational phenomena that Linneaus had used (Hull, 1988). In particular, Darwin's evolutionary theory provided a basis for understanding why there is a hierarchical arrangement about the categories in biological classification. The field of biological classification has continued to change. During the twentieth century, three different, competing approaches to biological classification have appeared (Hull, 1988). In oversimplified terms, one of these approaches emphasized the nomenclature and information retrieval purposes, the second focused on description, and the third was based on a theoretical view. The third view, the one based on theory, has become the dominant approach to biological classification (Nelson & Platnick, 1981).

4.03.3 DEVELOPMENT OF CLASSIFICATION SYSTEMS IN THE USA

The classification of mental disorders has an extensive history that can be traced back to some of the earliest writings known to man. A nineteenth century BC Egyptian writer discussed a disorder in women in which they would report vague and inconsistent physical symptoms that appeared to shift in body location over time (Veith, 1965). Psalm 102 provides an excellent clinical description of depression.

However, like many others areas of modern science, the first major commentaries on mental disorders were found in the writings of the Greeks. The Greek medical writers introduced four terms, all of which are still used today: "melancholia," "hysteria," "mania," and "paranoia." Melancholia was a Greek term that referred to a condition that now would be described by the word depression. Hippocrates believed that the sadness and the slowed bodily movements associated with this disorder were caused by an abundance of black bile, which he considered to be one of the four main ingredients in the human body. Hence, he named this disorder *melan* (black) + *cholia* (bile). The second term, hysteria, was the Greek word for the condition originally described by the Egyptians in which women had multiple, inconsistent and changing somatic complaints. The Hippocratic writers used the name of hysteria, which means pertaining to the uterus, because they believed that this disorder was caused by a dislodged, floating uterus. The last two terms were mania and paranoia. Mania, to the Greeks, referred to persons who were delusional. During the nineteenth century, individuals who were delusional but had few other symptoms were diagnosed with monomania (Berrios, 1993). Mania became an umbrella term for almost any type of psychotic state (Spitzka, 1883). The meaning of mania, however, changed again in the twentieth century to its contemporary denotation of grandiosity, excitement, expansiveness, and elation. The final Greek term, paranoia, has undergone a similar transformation. Paranoia initially meant craziness (*para* = abnormal + *nous* = mind). Now the term refers to people who are suspicious and often have delusions in which others are plotting against them.

After the Greeks, psychopathology did not attract much scientific interest until the nineteenth century. During the Middle Ages, mental disorders were associated with evilness. Thus, mental disorders were under the domain of religious authorities, not physicians or scientists. This approach to mental disorders began to change in the late 1700s as exemplified by the fact that King George III of England, who was psychotic for most of the last decade of his reign, received medical care rather than religious counseling.

The first major American physician to be interested in mental disorders was Benjamin Rush who, as a signer of the Declaration of Independence, was one of the prominent American physicians of the late eighteenth century. He was very interested in the forms of insanity. Rush also published a book on the topic which he titled *Medical inquires and observations upon the diseases of the mind* (Alexander & Selesnick, 1966). He believed in a theory of neurosis. According to this theory, mental disorders were caused by overstimulation of the nervous system. Thus, environmental phenomena such as the pace of urban living, overuse of alcohol, excessive sexual behavior, masturbation, and smoking were all seen as casual factors in the development of mental disorders. As a result, asylums were the appropriate way to treat insane patients. Asylums could provide the quiet and tranquility that was necessary to allow the nervous system to heal and to repair itself.

About the same time that Rush was writing about psychopathology in the USA, there was an important discovery in France that was to markedly influence thinking about mental disorders. In 1822, a physician named Bayle (Quetel, 1990) performed autopsies on a number of patients who presented with gradiose delusions and dementia (i.e., who had lost their mind from the French *de-* (not) + *ment* (mind)). Bayle discovered that all of the patients in his study had marked changes in their brains. In addition to their dementia, all of these patients developed motor paralysis before they died. The brains of these patients had shrunk to almost half the weight of a normal brain, the skin of the brain (i.e., the meninges and the arachnoid) was thickened, and the color of the brain was strikingly different from that of normal brains. Bayle's name for this disorder was chronic arachnitis since he believed that this disorder was caused by a chronic infection of arachnoid tissue (Quetel, 1990). Later, the common name for this disorder was changed to dementia paralytica, a descriptive name that referred to the combined presence of a psychosis together with the progressive paralysis of the patient's limbs.

The discovery of dementia paralytica was the first instance in which a mental disorder had been shown to be associated with demonstrable changes in the brain. A number of autopsy studies appeared in the medical journals. These studies attempted to identify the exact neuropathology of this disorder as well as to understand its cause. Dementia paralytica was also a clinically serious disorder because it accounted for about one-sixth of all admissions to insane asylums during the nineteenth century. The prognosis of the disorder was very poor because death typically would occur within three years of the diagnosis (Austin, 1859/1976). For most of the nineteenth century, many different etiologies were proposed as potential causes of this disorder. Austin (1859/1976), for instance, listed the following as moral causes of dementia paralytica: death of a son, sudden loss of two good situations, wife's insanity, worry, and commercial ruin.

With the increasing interest in psychopathology during the nineteenth century, a number of classifications for mental disorders appeared. One example of these classifications was published by William A. Hammond (Blustein, 1991). Hammond, like Freud, was a nineteenth century neurologist. As a young physician, Hammond had published a set of interesting experimental studies on human physiology. At the age of 34, he became Surgeon General for the US Army during the Civil War and was credited with a number of important innovations at the time including hospital design, the development of an ambulance corps, and the removal of a mercury compound from the medical formulary. His political clashes with the Secretary of War, however, led to his court martial and dismissal. After the Civil War, he moved to New York City and developed a lucrative private practice as a neurologist—a remarkable accomplishment during a time when most physicians were generalists. His interests extended to psychiatry and to writing novels as well as to physiology, studies of sleep, hypnosis, and the use of animal hormonal extracts. Hammond wrote extensively in scientific journals. He was one of the founders of the *Journal of Nervous and Mental Disease* which is still published. In addition, he authored important textbooks of neurology and psychiatry.

In Hammond's textbook of mental disorders, he argued that there were six possible principles that could be used to organize a classification system:

(i) anatomical (organized by the part of the brain that is affected);

(ii) physiological (organized by the physiological system in the brain);

(iii) etiological (supposed causes);

(iv) psychological (based upon a functional view of the mind);

(v) pathological (observable, morbid alterations in the brain); and

(vi) clinical (descriptive, based upon clusters of symptoms).

Of these six principles, Hammond said that the anatomical, the physiological, and the pathological are the best, but he could not use them because the science of his time was insufficient. Hammond also rejected the etiological organization of categories, because he felt that an etiological classification, given nineteenth century knowledge, would be too speculative. Thus, the main choice was between the clinical (descriptive) approach and the psychological (mentalistic) approach. Hammond preferred the latter because he thought that a classification which did not have a strong theoretical basis would fail.

Hammond adopted a functional view of psychology that was common in his day. He believed that mental functioning could be organized into four areas: perception, cognition, affect, and will. Hence, he organized his classification of mental disorders into six major headings:

(i) perceptual insanities (e.g., hallucinations);

(ii) intellectual insanities (e.g., delusional disorders);

(iii) emotional insanities (e.g., melancholia);

(iv) volitional insanities (e.g., abulomania);

(v) compound insanities (i.e., disorders affecting more than one area of the mind); and

(vi) constitutional insanities (i.e., disorders with specific causes such as choreic insanity).

There were a total of 47 specific categories of mental disorders that were organized under these six major headings. Most names of these specific categories would not be recognized by modern clinicians. The descriptions of these disorders, together with case histories that he included in this textbook do, however, suggest that many of the disorders he was discussing would have modern counterparts. For instance, under the heading "intellectual insanities," Hammond classified four disorders whose names seem odd by modern standards: intellectual monomania with exaltation, chronic intellectual monomania, reasoning mania, and intellectual subjective morbid impulses. In modern terms, these disorders probably would be called biopolar I disorder (manic episode), schizophrenia (continuous), narcissistic personality disorder, and obsessive compulsive disorder.

In Hammond's textbook, the lengthiest discussion was devoted to general paralysis, for which Hammond's name was dementia paralytica. As part of this discussion, Hammond included the proclamation by John Michler (quoted at the beginning of this chapter). In his discussion of general paralysis, Hammond emphasized the many medical symptoms associated with this disorder.

By the end of the nineteenth century, there were three broad theories about the etiology of this disorder. First, one school of thought believed that it was caused by alcoholism because the disorder primarily affected men, the age of onset was typically during the 30s and 40s (which is the same time of onset for severe alcoholism), and most men with dementia paralytica had substantial drinking histories. Second, was the theory that the disorder was caused by syphilis. Epidemiological surveys had found that over 80% of men with dementia paralytica had had syphilis. However, since no survey had documented 100% with a history of syphilis, many investigators suggested that syphilis was an important precondition to the development of dementia paralytica but was not the single cause. Hammond, for instance, was clear that syphilis was not the etiology because syphilis was associated with other forms of insanity. The third theory was more psychological in that the disorder was believed to be caused by moral depravity because persons who drank, who frequented prostitutes, and who were in the military were more likely to have the disorder. As additional evidence, dementia paralytica was known to be rare among priests and Quakers.

Research, attempting to provide evidence for or against these theories, was performed. For instance, a famous German psychiatrist named Kraft-Ebbing performed a study in which he injected serum from patients with syphilis into the blood streams of patients with dementia paralytica. Since it was known at the time that a person could only develop a syphilitic infection once, if any of the patients with dementia paralytica developed syphilis, it would prove that they had not had syphilis previously. Hence syphilis could not be the cause of the disorder. None of the 32 patients with dementia paralytica developed syphilis. Kraft-Ebbing concluded that syphilis was the cause of this disorder.

The conclusive evidence regarding the etiology of dementia paralytica occurred in the early twentieth century. In 1906, the bacillus that causes syphilis was isolated, and the Waserman test for syphilis was developed. Plaut (1911) demonstrated that patients with dementia paralytica had positive Waserman tests from blood samples and also from samples of cerebrospinal fluid. In 1913, two Americans, Noguchi and Moore, were able to identify the presence of the syphillitic baccilus in the brains of patients who had died from dementia paralytica (Quetel, 1990). The name of this disorder was changed again to reflect the new understanding of this disorder. It was called paresis or general paralysis associated with tertiary syphilis of the central nervous system. However, even after the discovery of the cause of dementia paralytica, the development of antibiotics to treat the disorder was another 30 years in the future. Thus, many patients were treated by inoculating them with malaria (Braslow, 1995).

4.03.4 KRAEPELIN

Another important development at the turn of the century was the international focus on the classificatory ideas of a German psychiatrist named Emil Kraepelin (Berrios & Hauser, 1988). Kraepelin was a researcher who initially learned his approach to research in a laboratory organized by Wundt, one of the founders of modern experimental psychology. After completing his medical degree, Kraepelin became the medical director for an insane asylum in east Prussia. While in that setting, Kraepelin published a number of experimental psychology studies on persons with mental disorders. He also began to write textbooks about psychopathology for German medical students. Like most textbook authors, Kraepelin organized his chapters around the major categories of mental disorders that he recognized. The sixth edition of Kraepelin's textbook (Kraepelin, 1902/1896) attracted major international attention because of two chapters in these texts.

One chapter was about a disorder that Kraepelin described as dementia praecox (praecox = early) which was a form of psychosis that had a typical age of onset in adolescence. Kraepelin recognized three subtypes to this disorder: hebephrenic, catatonic, and paranoid. Kraepelin's chapter on dementia praecox paralleled the immediately preceding chapter on dementia paralytica. Just as dementia praecox had three descriptive subtypes, dementia paralytica also had three descriptive subtypes: a depressed form, a grandiose form, and a paranoid form.

The second chapter to attract attention was what Kraepelin named manic-depressive insanity. Kraepelin's observations of patients in asylums had led him to believe that the mania and depression (= melancholia) had the same type of course when these patients were observed over time. Both were episodic disorders. Moreover, nineteenth century clinicians had recognized that there were some patients who went from episodes of mania to episodes of depression and vice versa. These observations led Kraepelin to hypothesize that mania and depression were essentially flip sides of the same coin. Hence, he combined, what had been recognized since the times of the ancient Greeks as two disorders, into one mental disorder.

In 1917, the newly formed American Psychiatric Association (APA) adopted a classification system that was quite similar to the classification contained in Kraepelin's sixth edition of his textbook. This early twentieth century American classification included the concepts of dementia praecox and manic-depressive disorder. The classification also adopted the fundamental Kraepelinian distinction between the organic disorders, the functional psychoses, and the neurotic/character disorders.

In 1932, the APA officially adopted a new classification system as part of the Standard Classified Nomenclature of Diseases (APA, 1933). This new classification, however, did not attract much attention (Menninger, 1963).

4.03.5 EARLY *DSMS* AND *ICDS*

World War II led to a renewed emphasis on classification. During the war, nearly 10% of all military discharges were for psychiatric reasons. By the time the war ended, there were four major competing classification systems at use in the USA: (i) the standard system adopted by the APA in 1932; (ii) the US Army classification; (iii) the US Navy classification; and (iv) the Veterans Administration system (Raines, 1952). In response to this disorganization, the APA formed a task force to create a system that would become standard in the USA. The result was the *Diagnostic and statistical manual of mental disorders* (*DSM*; APA, 1952). This classification is usually known by its abbreviated name: *DSM-I*. The *DSM-I* contained 108 different diagnostic categories.

The *DSM-I* was important for a number of reasons. First, the major rationale behind the *DSM-I* was to create a classification system that represented a consensus of contemporary thinking. Care was taken to include all diagnostic concepts that were popular in American psychiatry during the 1940s and 1950s. Thus, the *DSM-I* emphasized communication among professionals as the major purpose of classification and emphasized the need for psychiatric classification to be an accepted nomenclature that members of a profession can use to discuss their clinical cases. Consistent with this emphasis on communication, early versions of the *DSM-I* were revised, based on comments elicited in a questionnaire sent to 10% of the members of the APA. The *DSM-I* was finally adopted by a vote of the membership of the APA (Raines, 1952).

The emphasis on communication in the *DSM-I* led to a similar organizing movement at an international level. The international psychiatric community had adopted a classification of mental disorders that was part of the *International statistical classification of disease, injuries and causes of death* (6th ed.) (*ICD-6* World Health Organization (WHO), 1948). The first *ICD* had been created in 1900 and was a medical classification of causes of death. The *ICD-6* was the first edition to include all diseases, whether they led to death or not. The classification of mental disorders in the *ICD-6* did not gain broad acceptance. A committee, chaired by the British psychiatrist Stengel, was formed to review the classification systems used by various countries and to make any necessary recommendation for changes to the WHO. What Stengel (1959) found was a hodgepodge of diagnostic systems between, and sometimes within, different countries. Stengel despaired over the confused state of international classification and said that the *ICD-6* did not serve as a useful nomenclature. A positive note in his review, however, concerned the *DSM-I*, which Stengel considered an advance over the other national classifications because of its emphasis on representing a well-organized nomenclature for a country.

As a result of Stengel's review, there was an international movement to create a consensual system that would be adopted by the WHO. The final product was the mental disorders section of the *ICD-8*. In the USA, the APA revised its *DSM* classification to correspond with the *ICD-8*. The US version of the *ICD-8* was known as the *DSM-II* (APA, 1968). The *DSM-II* had 185 categories. These categories were subdivided by a hierarchical organizational system. First, there was a distinction between psychotic and nonpsychotic disorders. The psychotic disorders were further subdivided into organic and nonorganic disorders. The classification of the organic disorders was in terms of etiology (e.g., tumors, infections, heredity, etc.). The nonorganic psychotic disorders primarily contained the Kraepelinian categories of schizophrenia and manic-depressive insanity. The nonpsychotic disorders were subdivided into eight subheadings including the neuroses (now called anxiety disorders), personality disorders, mental retardation, etc.

4.03.6 NEO-KRAEPELINIANS

After the publication of the *DSM-II*, psychiatric classification became a very unpopular topic. There were three general lines of criticism that were aimed at classification. First, the diagnosis of mental disorders was unreliable as shown by empirical research. Second, a number of critics attacked the implicit medical model approach to psychopathology that was associated with the *DSM-I* and *DSM-II*. Third, sociologists became interested in a theory of labeling that suggested the process of classification was a process that stigmatized human beings who adopted unusual patterns of behavior and the act of diagnosis could lead to self-fulfilling prophecies.

The first of these criticisms was summarized in three different review articles by Kreitman (1961), Zubin (1967), and Spitzer and Fleiss (1974). All discussed various problems associated with the classification of mental disorders and why poor reliability was a significant issue. Zubin (1967) made an excellent case that the lack of uniform statistical procedures for estimating reliability was a serious methodological problem. Spitzer and Fleiss (1974) suggested a solution to this problem and showed how this solution could be applied retrospectively to earlier data. Kreitman (1961) probably had the most far-reaching analysis of the issue because he said that the unreliability problem had been overemphasized and that the more serious issue was the unexplored validity of diagnostic concepts.

The second issue criticism of the early *DSM*s and *ICD*s was the implicit acceptance of a medical model. Despite the dramatic etiological solution to dementia paralytica, most of the twentieth century research has been disappointing to those who believed that mental disorders are caused by underlying biological processes. Large amounts of research have attempted to discover the etiology of disorders such as schizophrenia, yet, despite interesting advances, a clear understanding of the cause of this disorder is not available. A psychiatrist named Thomas Szasz published a book titled *The myth of mental illness* (Szasz, 1961). He argued that mental disorders are not diseases, but instead are better conceptualized as "problems in living." He argued that psychiatrists had placed themselves into the role of moral policeman to control individuals with deviant behavior patterns. Szasz is now considered one of a group of critics of classification known by the title "antipsychiatrists." Others in this group are the British psychiatrist Laing (1967), the French psychoanalyst Lacan (1977), and recent authors such as Sarbin (1997), and Kirk and Kutchins (1992).

The third criticism of classification that became popular in the 1960s and 1970s was the labeling criticism. Sociologists such as Matza (1969) and Goffman (1961) suggested that the act of psychiatric diagnosis could lead to self-fulfilling prophecies in which the behavior of deviant individuals was constrained to become even more deviant. A dramatic demonstration of the labeling criticism was contained in a controversial paper published by Rosenhan (1973). In this paper, Rosenhan and his colleagues gained admission to mental hospitals even though they reported everything about themselves factually except their names and one auditory hallucination. All but one of these pseudopatients were admitted with a diagnosis of schizophrenia and all were released with a diagnosis of schizophrenia in remission. The pseudopatients commented that most of the patients were aware that they did not belong there, even though the hospital staff never figured that out. In addition, the experiences of the pseudopatients supported the labeling concern. For instance, one pseudopatient reported being bored while being on a ward and walking around. A nurse noticed him pacing and asked if he was feeling anxious. Following the publication of the Rosenhan paper, an issue of the *Journal of Abnormal Psychology* in 1975 was devoted to commentaries on this controversial paper.

Partially in reaction to these criticism of classification, a new school of thought was formed in psychiatry called the neo-Kraepelinians (Klerman, 1978). This group of psychiatrists, initially an active collection of psychiatric researchers at Washington University in St. Louis, believed that psychiatry, with its psychoanalytic emphasis, had drifted too far from its roots in medicine. The neo-Kraepelinians emphasized that psychiatry should be concerned with medical diseases, that extensive research was needed on the biological bases of psychopathology, and that much more emphasis needed to be placed upon classification if knowledge about psychopathology was to grow. Klerman (1978) summarized the perspective implicit in the neo-Kraepelinian approach to psychiatry by listing the following tenets:

(i) Psychiatry is a branch of medicine.

(ii) Psychiatry should utilize modern scientific methodologies and base its practice on scientific knowledge.

(iii) Psychiatry treats people who are sick and who require treatment.

(iv) There is a boundary between the normal and the sick.

(v) There are discrete mental illnesses. Mental illnesses are not myths. There is not one, but many mental illnesses. It is the task of scientific psychiatry, as of other medical specialties, to investigate the causes, diagnosis, and treatment of these mental illnesses.

(vi) The focus of psychiatric physicians should be particularly on the biological aspects of mental illness.

(vii) There should be an explicit and intentional concern with diagnosis and classification.

(viii) Diagnostic criteria should be codified, and a legitimate and valued area of research should be to validate such criteria by various techniques. Further, departments of psychiatry in medical schools should teach these criteria and not depreciate them, as has been the case for many years.

(ix) In research efforts directed at improving the reliability and validity of diagnosis and classification, statistical techniques should be utilized.

In 1972, a group of the psychiatric researchers at Washington University published a paper entitled "Diagnostic criteria for use in psychiatric research" (Feighner, Robins, Guze, Woodruff, Winokur, & Munoz, 1972). This paper listed 15 mental disorders that they believed had sufficient empirical evidence to establish their validity, and listed a set of diagnostic criteria for defining these disorders. The authors argued that a major problem in research about these disorders had stemmed from the lack of uniform definitions by different researchers of the disorders. They suggested that future research on any of these disorders should utilize the diagnostic criteria proposed in their paper.

The paper by Feighner et al. had a dramatic impact on American psychiatry. It was a heavily cited paper, probably the most frequently referenced journal article of the 1970s in psychiatry. The diagnostic criteria were immediately adopted and became the standard for psychiatric research. Moreover, the 15 categories described by Feighner et al. were expanded into a much larger set of categories, focusing primarily on the schizophrenic and affective disorders (Spitzer, Endicott, & Robins, 1975). This new classification was called the Research Diagnostic Criteria (RDC) and had an associated structured interview known as the SADS. Since the lead author of the RDC, Robert Spitzer, had been appointed as the new chairperson responsible for organizing the *DSM-III*, the RDC became the initial foundation from which the *DSM-III* developed.

4.03.7 *DSM-III*, *DSM-III-R*, AND *DSM-IV*

The *DSM-III* (APA, 1980) was a revolutionary classification. First, unlike the *DSM-I* and *DSM-II*, which had emphasized using consensus as the major organizing principle, the *DSM-III* attempted to be a classification based on scientific evidence rather than clinical consensus. For instance, the classification of depression was very different from the view of depression in the *DSM-I* and *DSM-II*, largely because of family history data gathered in research studies performed by the neo-Kraepelinians. In the earlier

*DSM*s, the primary separation of affective disorders was in terms of a psychotic vs. neurotic distinction. The *DSM-III* dropped this differentiation and, instead, emphasized a separation of bipolar vs. unipolar mood disorders. Second, the *DSM-III* discontinued the use of prose definitions of the mental disorders. The neo-Kraepelinians were impressed by the research data suggesting that the reliability of psychiatric classification, as represented in the *DSM-I* and *DSM-II*, was less than optimal (Spitzer & Fleiss, 1974). To try to help improve diagnostic reliability, virtually all mental disorders in the *DSM-III* were defined using diagnostic criteria stimulated by the innovative system used in the Feighner et al. paper. Third, the *DSM-III* was a multiaxial classification. Because the *DSM-I* and *DSM-II* were "committee products," the subsections of these classifications had different implicit organizing principles. For instance, in the *DSM-I/DSM-II*, the organic brain syndromes were organized by etiology, the psychotic disorders were organized by syndromes, and the neurotic disorders were organized according to ideas from psychoanalytic theory. In order to avoid the confusion inherent in the use of multiple organizing principles, the *DSM-III* adopted a multiaxial system that permitted the separate description of the patient's psychopathology syndrome (Axis I), personality style (Axis II), medical etiology (Axis III), environmental factors (Axis IV), and role disturbances (Axis V). The *DSM-III* was published in 1980 and contained 265 mental disorders. Moreover, the size of the manuscript for the *DSM-III* was 482 pages, a huge increase over the 92 pages of the *DSM-II*.

The revolutionary impact of the *DSM-III* led to changes in many areas of the mental health professions. One area of impact was in terms of research. As soon as versions of the *DSM-III* began to be disseminated to researchers interested in mental disorders, new studies began to appear that explored the adequacy of the diagnostic criteria used in this classification. The *DSM-III* was a marked stimulus for descriptive research in psychiatry and in the other mental health professions. Another area of impact was political. There was a major controversy that erupted in the late 1970s over the issue of whether the term "neurosis" should appear in the *DSM-III*. Spitzer and the neo-Kraepelinians had exorcized this term from the classification because of its psychoanalytic associations. The psychoanalysts lobbied intensely within the APA to have the term reintroduced. Although a compromise was achieved (Bayer, 1981), the psychoanalysts lost ground in this struggle, and their influence in organized psychiatry has continued to wane since that time. A third area of impact for the *DSM-III* was economic. The *DSM-III* became very popular, sold well in the USA, and even became a surprisingly large seller to the international community as translations appeared. The sizeable revenues that accrued to the APA led to the formation of the American Psychiatric Press, which published subsequent versions of the *DSM* as well as many other books of clinical interest.

Despite its innovations and generally positive acceptance by mental health professionals, a number of criticisms were leveled at the *DSM-III*. One focus of criticism concerned the diagnostic criteria. Despite the intention to make decisions about the classificatory categories using scientific evidence, most diagnostic criteria were based on the intuitions of experts in the field. In addition, even though the goal when formulating diagnostic criteria was to make them as behavioral and explicit as possible, not all criteria met this goal. Consider part of the *DSM-III* criteria for histrionic personality disorder, for instance.

> Characteristic disturbances in interpersonal relationships as indicated by at least two of the following:
>
> 1) perceived by others as shallow and lacking genuineness, even if superficially warm and charming
> 2) egocentric, self-indulgent and inconsiderate of others
> 3) vain and demanding
> 4) dependent, helpless, constantly seeking reassurance
> 5) prone to manipulative suicidal threats, gestures or attempts

Note that common language terms such as "shallow" were highly subjective. In addition, a criterion such as 3) requires an inference about motivations and reasons for behavior, rather than direct observation of behaviors. Finally, subsequent research showed that criterion 5) above actually was observed more frequently in borderline rather than histrionic patients (Stangl, Pfohl, Zimmerman, Bowers, & Corenthal, 1985).

A second major criticism of the *DSM-III* concerned the multiaxial system. First, diagnosing multiple axes required increased time and effort by clinicians, an exercise they were unlikely to do unless they were certain that the gain in information was significant. Second, the relative emphasis on these five axes in the *DSM-III* was sizeably different. In the *DSM-III* manual, almost 300 pages were devoted to defining the Axis I disorders, another 39 pages were spent on Axis II disorders, whereas only two pages each were devoted to Axes IV and V.

Moreover, Axes I and II were assessed using diagnostic categories, whereas Axes IV and V were measured using relatively crude, ordinal rating scales. Third, the choice of particular axes was also criticized. For instance Rutter, Shaffer, and Shepard (1975) had advocated the use of one axis for the clinical syndrome in childhood disorders with a second focusing on intellectual level. Instead, both clinical syndromes and mental retardation were Axis I disorders in the *DSM-III*. A group of psychoanalysts argued that defense mechanisms should have been included as a sixth axis. Psychiatric nurses advocated an additional axis for a nursing diagnosis, relevant to the level of care required by a patient.

Only seven years later, a revision to the DSM-III was published. This version, known as the *DSM-III-R* (APA, 1987), was intended primarily to update diagnostic criteria using the research that had been stimulated by the *DSM-III*. It was called a revision because the goal was to keep the changes small. However, the differences between the *DSM-III* and the *DSM-III-R* were substantial. Changes included renaming some categories (e.g., paranoid disorder was renamed delusional disorder), changes in specific criteria for disorders (e.g., the criteria for schizoaffective disorder), and reorganization of categories (e.g., panic disorder and agoraphobia were explicitly linked). In addition, six diagnostic categories originally in the *DSM-III* were deleted (e.g., egodystonic homosexuality and attention deficit disorder without hyperactivity) while a number of new specific disorders were added (e.g., body dysmorphic disorder and trichotillomania). As a result, the *DSM-III-R* contained 297 categories compared to the 264 categories in the *DSM-III*.

Associated with the *DSM-III-R* was the development of a major controversy that had political overtones. Among the changes proposed for the *DSM-III-R* was the addition of three new disorders: premenstrual syndrome (PMS), masochistic personality disorder and paraphilic rapism. These additions raised the ire of a number of groups, especially feminists. Concerning PMS, feminists argued that the inclusion of this disorder into the *DSM* would be the implicit assumption that the emotional state of women can be blamed on their biology. If it were to be a disorder, the feminists argued that PMS should be classified as a gynecological disorder rather than a psychiatric disorder. Masochistic personality disorder had been suggested for inclusion by psychoanalysts who pointed to the extensive literature on this category. Feminists, however, believed that this diagnosis would be assigned to women who had been physically or sexually abused. Thus, this diagnosis would have the unfortunate consequence of blaming these women for their roles as victims. Finally, the proposal to include paraphilic rapism was also attacked. The critics argued that this diagnosis would allow chronic rapists to escape punishment for their crimes because their behaviors could be attributed to a mental disorder. Thus, these men would not be held responsible for their behaviors.

Because of the ensuing controversy, a compromise somewhat similar to the earlier compromises about homosexuality and neurosis was attempted. The authors of the *DSM-III-R* revised the names of the first two disorders (PMS and masochistic personality disorder) to periluteal phase dysphoric disorder and self-defeating personality disorder. They also deleted the proposal to add paraphilic rapism. In addition, another disorder, sadistic personality disorder, was added presumably to blame abuser as well as victims, thereby balancing the potential antifeminine connotations of self-defeating/masochistic personality disorder. This compromise was not successful. As a result, the executive committee for the American Psychiatric Classification decided not to include these categories in the body of the *DSM-III-R*. Instead, they were placed in an appendix as disorders needing more research (Walker, 1987).

The *DSM-IV* was published in 1994, contained 354 categories, and was 886 pages in length, a 60% increase over the *DSM-III* and almost seven times longer than the *DSM-II* (APA, 1994). There are 17 major categories in the *DSM-IV*:

disorders usually first diagnosed in childhood
cognitive disorders
mental disorders due to a general medical condition
substance-related disorders
schizophrenia and other psychotic disorders
mood disorders
anxiety disorders
somatoform disorders
factitious disorders
dissociative disorders
sexual disorders
eating disorders
sleep disorders
impulse control disorders
adjustment disorders
personality disorders
other conditions that may be a focus of clinical attention

The *DSM-IV* retained a multiaxial system and recognized five axes (dimensions) along which patient conditions should be coded:

Axis I clinical disorders
Axis II personality disorders/mental retardation
Axis III general medical conditions
Axis IV psychosocial and environmental problems
Axis V global assessment of functioning

As with the *DSM-III-R*, a major focus in the *DSM-IV* revision concerned diagnostic criteria. A total of 201 specific diagnoses in the *DSM-IV* were defined using diagnostic criteria. The average number of criteria per diagnosis was almost eight. Using this estimate, the *DSM-IV* contains slightly over 1500 diagnostic criteria for the 201 diagnoses.

To give the reader a glimpse of how the diagnostic criteria have changed from the *DSM-III* to the *DSM-IV*, the criteria for histrionic personality disorder are listed below:

> A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
>
> (1) is uncomfortable in situations in which he or she is not the center of attention
> (2) interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
> (3) displays rapidly shifting and shallow expression of emotions
> (4) consistently uses physical appearance to draw attention to oneself
> (5) has a style of speech that is excessively impressionistic and lacking in detail
> (6) shows self-dramatization, theatricality, and exaggerated expression of emotion
> (7) is suggestible, i.e., easily influenced by others or circumstances
> (8) considers relationships to be more intimate than they actually are

In addition to presenting diagnostic criteria, the *DSM-IV* contains supplementary information about the mental disorders in its system. For instance, there are three pages of information about histrionic personality disorder including

diagnostic features (prose description of symptoms)
associated features and disorders (mental disorders that are likely to co-occur)
specific culture, age and gender features
prevalence
differential diagnosis (how to differentiate the disorder from others with which it is likely to be confused)

In order to help ensure that the *DSM-IV* would be the best possible classification of mental disorders, the steering committee for this classification contained 27 members, including four psychologists. Reporting to this committee were 13 work groups composed of 5–16 members. Each work group had a large number of advisors (typically over 20 per work group).

There were three major steps associated with the activities of each work group. First, all work groups performed extensive literature reviews of the disorders under their responsibility. Many of these literature reviews were published in the journal literature. Second, the work groups solicited contributions of descriptive data from researchers in the field. Using these data, the work groups reanalyzed the data to decide which diagnostic criteria needed revision. Third, a series of field trials was performed on specific topics. For instance, the personality disorders work group performed a multicenter study on antisocial personality disorder which led to a significant alteration in the diagnostic criteria for that disorder.

The *DSM-IV* was not without controversy. For instance, the issues that had been raised in the *DSM-III-R* regarding premenstrual syndrome, masochistic personality disorder, and sadistic personality disorder continued in the *DSM-IV*. Interestingly, none of these three disorders were included in the *DSM-IV*. In fact, two (masochistic and sadistic personality disorders) completely disappeared from the classification. PMS remained in an appendix as a disorder "for further study." Interestingly, 17 other disorders joined PMS in this appendix as did three possible new axes for the multiaxial system (defense mechanisms, interpersonal functioning, and occupational functioning).

Earlier editions of the *DSM* had few, if any, references to document the sources for any factual claims in these classifications. The *DSM-IV* attempt to overcome this problem was by publishing a five-volume companion set of sourcebooks. These sourcebooks are edited papers by members of the work groups. The intent of the sourcebooks is to provide a scholarly basis for understanding the specific decisions that were made by the work groups.

4.03.8 *ICD-9, ICD-9-CM,* AND *ICD-10*

Earlier in this chapter, the point was made that the *DSM-II* and *ICD-8* were virtually identical because the American psychiatric community had joined an international movement to create a consensual classification. With the revolutionary *DSM-III*, American psychiatry reversed itself and created a radically new classification based upon the purpose of description, rather than emphasizing a system that would be acceptable world-wide.

The editions of the *ICD*s were intended to be revised every 10 years. The *ICD-8* was published in 1966; the *ICD-9* came out in 1977. The mental disorders section of the *ICD-9* was very similar to the *ICD-8/DSM-II* (WHO, 1978). The psychotic/nonpsychotic distinction was the primary hierarchical distinction among categories. The psychotic disorders were further subdivided into organic and functional psychoses. There were 215 categories in this system, and the *ICD-9* was published in a monograph that was 95 pages in length.

The USA has signed an international treaty that obliges it to use the *ICD* as the official medical classification. Thus, when the *DSM-III* was created, an odd numeric coding scheme was incorporated so that the *DSM-III* categories could be incorporated with the *ICD-9* framework. To understand this, below is an overview of the specific diagnostic categories under the general heading of anxiety disorders in the *DSM-III*:

Phobic disorders
300.21 Agoraphobia with panic attacks
300.22 Agoraphobia without panic attacks
300.23 Social phobia
300.29 Simple phobia
Anxiety states
300.01 Panic disorder
300.02 Generalized anxiety disorder
300.30 Obsessive compulsive disorder
Post-traumatic stress disorder
308.30 Acute
309.81 Chronic or delayed
300.00 Atypical anxiety disorder

Notice that the coding scheme for the anxiety disorders in the *DSM-III* is not what one might expect. Most of the anxiety disorders are coded with 300.xx numbers. However, the two forms of post-traumatic stress disorder are coded 308.30 and 309.81. Notice also that the first number after the decimal point is somewhat irregular. The phobic disorders, listed first in the *DSM-III*, are given 300.2x codes whereas the anxiety states are coded 300.0x or 300.30.

To understand why the *DSM-III* codes appear this way, below is a listing of the specific neurotic disorders in the *ICD-9*:

Mental disorders (290–319)
Nonpsychotic mental disorders (300–316)
Neurotic disorders (300)
300.0 Anxiety states
300.1 Hysteria
300.2 Phobic states
300.3 Obsessive-compulsive disorders
300.4 Neurotic depression
300.5 Neurasthenia
300.6 Depersonalization syndrome
300.7 Hypochondriasis
300.8 Other neurotic disorders
300.9 Unspecified

In the *ICD-9* system, all diagnoses have four-digit codes. The codes for all mental disorders range from 290 to 319. The 29x disorders are the psychotic disorders; 300–315 are reserved for nonpsychotic disorders; and 316–318 are codes for classifying mental retardation. The first subheading under the nonpsychotic disorder is the neurotic disorders. Notice that this subheading includes what the *DSM-III* recognizes as anxiety disorders but it also includes categories that the *DSM-III* placed under other headings (e.g., neurotic depression = dysthymic disorder and depersonalization syndrome). Because the *DSM-III* anxiety disorders were mostly found under the *ICD-9* neurotic disorders, these categories were given 300.xx codes. However, post-traumatic stress disorder (chronic; PTSD) was given a code number of 309.89 because it was included under the general *ICD-9* heading of adjustment reactions. Notice also that PTSD has an xxx.8 coding. In the *ICD-9* coding system, all diagnoses with an xxx.8 code represent country-specific categories that are generally recognized by the international psychiatric community. Thus, PTSD (309.89) is a US category that has no clear equivalent in the international diagnostic system. Another *DSM-III* category with a coding that reflects a similar status is borderline personality disorder (301.83).

In order to blend the *DSM-III* with the *ICD-9* so that a consistent coding system would be used, a US version of the *ICD-9* was created. This new version was the *ICD-9-CM* (where CM stands for "clinical manual"). The *ICD-9-CM* is the official coding system that all physicians and mental health professionals must use when assigning diagnostic codes. However, American clinicians do not need to refer to the *ICD-9-CM* because the applicable codes are listed in the printed versions of the *DSM-III*, *DSM-III-R* and *DSM-IV*.

As noted earlier, the *DSM-III* and its successors (*DSM-III-R* and *DSM-IV*) were resounding successes. Not only did these systems become dominant in the USA, but they also achieved substantial popularity among European mental health professionals (Mezzich, Fabrega, Mezzich, & Coffman, 1985). The proponents of the *ICD* were somewhat resentful (Kendell, 1991). Thus, when the *ICD-10* was created, substantial changes were made that utilized innovations from the *DSM-III*.

First, like the *DSM-III*, the *ICD-10* went through extensive field testing (Regier, Klaeber, Roper, Rae, & Sartorius, 1994). There were two major goals in the field testing: (i) to ensure that the *ICD-10* could be used in a reliable way across clinicians, and (ii) to examine the acceptability of the mental disorder categories contained in this system. The data reported regarding both of these goals have given a favorable view of the *ICD-10*.

The second important innovation of the *ICD-10* is that the mental disorders section is published in two forms. One form, the blue manual, is subtitled *Clinical descriptions and diagnostic guidelines* (WHO, 1992). The blue manual contains prose definitions of categories and is primarily intended for clinical use. The other, the green manual, is like the *DSM-III* in that the categories are defined using explicit diagnostic criteria with rules regarding how many criteria must be met in order for a diagnosis to be made (WHO, 1993). The green manual is intended for research use.

The complete *ICD-10* is organized into a series of 21 chapters, one of which is Chapter V (labeled with the prefix F) about "Mental and behavioural disorders." Other chapters in the *ICD-10* are:

Chapter I A–B Infections and parasitic diseases

Chapter II C–D Neoplasms

Chapter X J Diseases of the respiratory system

Chapter XXI Z Factors influencing health status and contact with health services

In terms of classificatory size, the mental disorders section of the *ICD-10* and the *DSM-IV* are reasonably similar. The *DSM-IV* contains 354 categories organized under 17 major headings. The *ICD-10* has 389 categories that are structured under 10 major headings. One ironic feature of the *ICD-10* is that it did not adopt a multiaxial system of classification. This decision is ironic because the idea originated in Europe, most prominently by a Swedish psychiatrist, Essen-Moller (1971).

4.03.9 CONTROVERSIES AND ISSUES

Although the *DSM-III* and its successors are usually viewed as substantial improvements in the classification of mental disorders, a number of controversies and issues still remain concerning the classification of mental disorders. The remainder of this chapter attempts to provide an overview of some of these issues.

4.03.9.1 Organizational Models of Classification

There are four organizational models of classification that have been frequently discussed in the literature. Often these models are seen as competing and incompatible. For instance, most discussions of the first two models, the categorical and the dimensional, are presented as if the mental health professions must choose between them. However, hybrid models are possible (Skinner, 1986) and perhaps even the most probable.

Mental disorders are usually discussed as if they are categories. Thus, a categorical model is often implicitly assumed to be the structural model for psychopathology (Kendell, 1975). The tenets of this model are listed below:

> 1.1 The basic objects of a psychiatric classification are patients
> 1.2 Categories should be discrete, in the sense that the conditions for membership should be able to be clearly ascertained
> 1.3 Patients either belong or do not belong to specified classes (categories)
> 1.4 The members of a category should be relatively homogeneous
> 1.5 Categories may or may not overlap
> 1.6 In the borderline areas where categories may overlap, the number of overlapping patients should be relatively small
> 1.7 Cluster analytic methods can be used to initially identify categories
> Discriminant analysis is used to validate categories. (Blashfield, 1991, p. 14)

The *DSM*s, particularly the *DSM-III* and its successors, are seen as fitting a categorical model. According to the categorical model, the unit of analysis is the patient. Diagnoses refer to classes of patients. Patients either are or are not the members of the categories. The categorical model assumes that some type of definitional rule exists by which the membership in a category can be determined. Moreover, membership in a category is considered to be a discrete, all-or-nothing event. An animal is either a cat or not a cat. A patient is either a schizophrenic or not a schizophrenic.

An important assumption of the categorical model is that members of a category are relatively homogeneous. All animals that belong to the class of "birds" should be reasonably similar morphologically. This is not to say that all birds must be alike. Certainly a robin and sparrow have a number of obvious differences. Yet they are more like each other than either is to a lynx, for instance. In the same way, two schizophrenic patients should be relatively similar. Both may have different symptom pictures, but their symptom pictures should be more similar to each other than either is to an antisocial patient (Lorr, 1966).

Classes in a categorical model may or may not overlap. Most uses of the categorical model typically assume that nonoverlapping categories are an ideal condition, but recognize that this condition may not always happen. Thus, overlap among categories is often treated like measurement error—a condition to be tolerated, but minimized. However, there are categorical models that have been developed in which the categories are assumed to overlap (Jardine & Sibson, 1971; Zadeh, 1965). In these models, overlap is not error. Categories are fuzzy sets whose boundaries of membership do not need to result in mutually exclusive groupings.

According to the assumption of relative homogeneity, the number of patients who clearly belong to one and only one category should be relatively frequent, whereas patients who fall in the overlapping, borderline areas between categories should be relatively infrequent. A sparrow–lynx should not occur if categories are to have the necessary homogeneity that allows them to be separable constructs (Grinker, Werble, & Drye, 1968).

Finally, the methods that have been developed to find the boundaries among categories are called cluster analytic methods (Everitt, 1974). Generally, these methods analyze a large matrix of descriptive data on patients, and attempt to form clusters (categories) of relatively homogeneous patients in terms of the descriptive variables that were gathered on the patients. Cluster analysis was used in the 1960s and 1970s to create new descriptive classifications. In the last decade, most researchers have abandoned the use of these methods because of pragmatic difficulties in their application and because of unsolved statistical issues. Meehl, however, has developed a related method for isolating categories that he believes has promise (Meehl, 1995).

Although the categorical model, as presented above, seems to be a common sense model of psychiatric classification, the recent *DSM*s clearly do not adhere to this model. First, as noted above, a categorical model assumes that the unit of analysis is the patient and that groups of patients are members of similar sets called mental disorders. The authors of the *DSM-III*, *DSM-III-R and DSM-IV* explicitly reject this approach. They state that these classifications are not intended to classify individual patients (Spitzer & Williams, 1987). Instead, these recent *DSM*s state that they are classifying disorders (rather than patients).

A second structural model is the dimensional model. The tenets for this model are:

> 2.1 The basic unit of the dimensional model is a descriptive variable (e.g., a symptom, a scale from a self-report test, a laboratory value, etc.)
> 2.2 Dimensions refer to higher-order, abstract variables
> 2.3 A dimension refers to a set of correlated descriptive variables
> 2.4 There are a relatively small number of dimensions compared to the number of descriptive variables, yet the dimensions account for almost as much reliable variance as do the larger number of descriptive variables
> 2.5 Dimensions themselves may be correlated or independent
> 2.6 The methods used to identify dimensions are exploratory factor analysis and multidimensional scaling. Confirmatory factor analysis can be used to test a specific dimensional model. (Blashfield, 1991, p. 15)

For the dimensional model, the basic units of analysis are the descriptive variables. Thus, the dimensional model focuses on symptoms, behaviors, diagnostic criteria, scales from self-report tests, and the like. The dimensional model summarizes these descriptive variables by forming higher-order abstract variables that can serve to represent the original measurement variables. Each of these higher-order abstract variables constitutes a dimension through its conceptualization as occurring on a continua. Patients can have scores anywhere along these dimensions.

A major test of a dimensional model is parsimony. The specific dimensions in such a system should account for most of the systematic, reliable variance that exists within the original set of descriptive variables. If the dimensions do not account for the reliable variance in the original descriptive variables, then using the dimensions will sacrifice a great deal of information and the original variables should be used rather than the smaller set of dimensions.

A third structural model that is often discussed regarding the classification of mental disorders is a disease model. The basic assumption in this model is that all diagnostic categories refer to medical diseases (Wing, 1978). In effect, this model is a modern extension of Griesinger's famous nineteenth-century dictum that all mental disorders are diseases of the brain (Stromgren, 1991). The tenets of the disease model are:

> 3.1 The fundamental units are biological diseases of individual patients (essentialism)
> 3.2 Each diagnosis refers to a discrete disease
> 3.3 Diagnostic algorithms specify objective rules for combining symptoms to reach a diagnosis
> 3.4 Adequate reliability is necessary before any type of validity can be established

3.5 Good internal validity will show that the category refers clearly described patterns of symptoms
3.6 Good external validity will mean that the diagnosis can be used to predict prognosis, course and treatment response. (Blashfield, 1991, p. 8)

Some authors have assumed that a categorical model and a disease model are the same. These models are not identical. A categorical is neutral about the existential status of the categories in its system. A disease model adopts a stronger view. Diseases do have an existential status. Diseases are real. The goal of medical research is to identify, describe, understand and eventually treat these diseases. This belief in the reality of diseases is associated with a broader view about the status of scientific concepts known as essentialism.

Notice also that diseases are not necessarily categorical, at least as this model was described above. For instance, more than one disease can occur in the same patient. In fact, some diseases are very likely to co-occur (e.g., certain sarcomas have high frequency in patients with AIDS). Thus, diseases do not refer to mutually exclusive sets. In addition, there are diseases that are conceptualized as dimensional constructs. Hypertension is the most common example. Patients with hypertension vary along a continuum. A categorical scaling of this continuum is possible, but imposing a categorical separation on this continuum is arbitrary.

The fourth model of classification is the prototype model. Cantor, Smith, French, and Mezzich (1980) have suggested that this model is superior to the implicit categorical model of psychiatric classification. For those readers who do not know what the prototype model is, the easiest way to conceptualize this model is through an example.

According to the prototype model, if a mother wanted to teach a child what "anger" means, she would not say "Steven, you need to understand that anger is an emotion that many of us feel when we are frustrated or upset." Instead, at some point when little Steven is upset because he has to go to bed and he tries to hit his mother, she would say "I know that you are angry, Steven, but it is time to go to bed." And on another day, when Steven is upset because another child took one of his toys, his mother might say, "You are feeling angry, Steven. Being angry is natural, but you should not hit the other child. Maybe if you ask Carol she will return your toy."

In effect, a child learns a concept by being presented with instances of the concept. Once the child is able to associate the instances with a verbal label (i.e., the word "angry"), then the child will have a grasp of the concept. Later, the child will learn to abstract the essential features of the concept. This occurs by making observations about similarities that occur among instances of the concept (e.g., internal feelings, interpersonal context, etc.). Russell and Fehr (1994) provide an interesting and more complete discussion of the concept of anger from a prototype perspective.

Another important aspect of the prototype model is the idea that not all instances of a concept are equally good representatives of the concept. A robin, for instance, is a good exemplar of a bird. Robins are about the same size as most birds; they have feathers; they can fly; etc. Penguins, however, are not a good exemplar. Penguins are larger than most birds; they cannot fly; they do have feathers, although, to a child, their covering probably seems more like fur than feathers; etc.

The above presentation of the prototype model is easy to understand and seems like a common-sense view of classification. However, advocates of the prototype model argue that this model is radically different than a categorical model (Barasalou, 1992; Russell, 1991). According to the categorical model, classificatory concepts are defined by listing the features that are sufficient for making a diagnosis. If a given instance has a sufficient number of these features, then that instance is a member of the classificatory concept. Moreover, all members of a concept are equal. A square is a square. One square is not squarer than another square. In contrast, the prototype model does stipulate that some instances of a concept are better exemplars than others. The Glenn Close character in *Fatal attraction* is a better representation of borderline personality disorder than the Jessica Walter character in *Play Misty for me*.

The basic tenets of the prototype model are presented below:

4.1 Diagnoses are concepts that mental health professionals use (nominalism)
4.2 Categories are not discrete
4.3 There is a graded membership among different instances of a concept
4.4 Categories are defined by exemplars
4.5 Features (symptoms) are neither necessary nor sufficient to determine membership
4.6 Membership in a category is correlated with number of features (symptoms) that a patient has. (Blashfield, 1991, p. 11)

The major difference between the disease and the prototype model is that the latter is associated with nominalism. Nominalism is the position that the names of diseases are just convenient fictions that clinicians use to organize information. Diagnostic terms do not have some underlying reality of their own. Diagnostic concepts are names. These concepts exist simply to meet some functional goal.

The preceding discussion of organizational models of the classification of psychopathology is overly simplistic. Each of these models, when examined more closely, can become quite complex, and the apparent distinctions between the models blur. Two instances of this complexity will be described. First, although the categorical and dimensional are usually presented as if they are competing and antagonistic, Skinner (1986) has suggested that these models are actually complementary. He suggested that the measurement model associated with a dimensional perspective is the more fundamental of the two models. The dimensional model only assumes that, in order to assess a patient, a clinician should gather information on specific descriptive variables that are correlated and that can be summarized by higher-order variables (dimensions). The categorical model also assumes that descriptive variables can be sorted into dimensions. But, in addition, the categorical model asserts that the patients themselves "cluster" into groups that are relatively homogeneous on these dimensions. Thus, from Skinner's hybrid perspective, a pure categorical model makes stronger assumptions about descriptive data than does a dimensional model. However, psychological models of human social cognition suggest that categorical models are more basic than are dimensional models (Wyer & Srull, 1989).

A second example of the complexity of these models is associated with Barsalou's distinction between "prototype" and "exemplar" models. There are two types of approach that can be used to define a concept: intensional definitions and extensional definitions. An intensional definition lists the features that can be used to separate the concept from related concepts (e.g., a square is a four-sided closed figure whose sides are equally long and occur at right angles to each other). In contrast, an extensional definition is a definition by listing the members of the category (e.g., the 1957 New York Yankees included Roger Marris, Yogi Berra, Micky Mantle, etc.). Barsalou says that a prototype model uses an intensional definition for categories in which the prototype represents the average (centroid) of the concept. Using the example of a child learning about birds, Barasalou suggests that the reason that a robin is a prototype for bird, whereas a penguin is not, is that robins have the average features of most birds (small size, bright coloring, migration, food choices, etc.). Penguins, in contrast, are statistically unusual on these dimensions. An exemplar model, according to Barsalou, uses a particular type of extensional definition in which a concept is defined by an outstanding or exemplary instance of the concept. Thus, Micky Mantle might be a good exemplar of the 1957 New York Yankees even though Mantle's batting prowess was hardly average. In the same way, Abraham Lincoln might be seen as exemplar of American presidents, even though he was not average for this set of individuals.

4.03.9.2 Concept of Disease

The discussion of the disease model vs. the prototype model led to a brief introduction regarding the dualism of essentialism vs. nominalism. This dualism is associated with a complicated problem that has bothered writers about classification throughout the last two centuries. What is a disease? Do the two concepts of "mental disease" and "mental disorder" have the same meaning? To discuss the issues associated with the meaning of "disease," the writings of a British internist named Scadding will be discussed. At the end of this section, other approaches to the concepts of "disease" and "disorder" are briefly introduced.

Scadding's (1959) first attempt to discuss the meaning of disease occurred in a short essay. This essay offered his first general definition of disease which read:

> The term "a disease" refers to those abnormal phenomena which are common to a group of living organisms with disturbed structure or function, the group being defined in the same way.

In effect, Scadding was saying that a disease was associated with a cluster of signs and symptoms (i.e., abnormal phenomena) that are associated with some functional or structural disturbance in the human body. Scadding went on to argue that a disease had (i) defining characteristics and (ii) diagnostic criteria. The defining characteristics refer to the indications that prove the presence of the disease (e.g., locating syphilitic bacilli in the brains of individuals with paresis). In contrast, the diagnostic criteria are signs and symptoms of the disease that may or may not be present (e.g., motor paralysis, grandiose delusions, and sluggish pupillary response to light would be possible diagnostic criteria for paresis).

Ten years later, Scadding (1969) revised his definition of disease to read as follows:

> A disease is the sum of the abnormal phenomena displayed by a group of living organisms in association with a specified common characteristic or set of characteristics by which they differ from the norm for their species in such a way as to place them at biological disadvantage.

There are four important points to note about this second definition of disease. First, the emphasis is on abnormal phenomena. Scadding wanted to be quite clear that the name of the disease does not refer to the etiologic agent causing the disease. That is, tuberculosis is not simply defined by the presence of a particular bacterium, *Mycobacterium tuberculosis*. To have tuberculosis a patient must manifest the symptoms of the disease as well as the anatomical changes (i.e., the formation of characteristic lesions called tubercles in the lung) associated with this disease. This distinction is important because there are other bacilli, besides *Mycobacterium tuberculosis*, which can cause these lesions and the symptom pattern of tuberculosis.

Second, the definition contains the rather vague phrase "common characteristic." Scadding argued that there are three general ways of characterizing any individual disease: (i) a clinical-descriptive approach, (ii) a morbid anatomical approach, and (iii) an etiological approach. (Note that these approaches were presented almost a century earlier by Hammond (1883), as previously discussed.) The clinical-descriptive approach is simply the description of the "syndrome." That is, the clinical-descriptive approach outlines a loose cluster of signs and symptoms that are correlated in their appearance in patients. For instance, the clinical-descriptive approach to defining diabetes focuses on frequent urination, an intense thirst, and rapid loss of weight as indications of this disorder. The clinical-descriptive approach dominated when the *DSM-III* and its successors were created. The second approach concerns morbid anatomy. This refers to the anatomical changes in the body's structure associated with the disease. For diabetes mellitus, a morbid anatomy view might define this disease in terms of the destruction of β-insulin-producing cells in the pancreas. Finally, the etiological approach would be to define a disease in terms of the syndrome caused by a known and specifiable etiological process. For Type I diabetes mellitus, this might be an autoimmune process whose exact details have yet to be specified. For paresis, the etiological agent is the effect of the syphilitic bacillus on the central nervous system of the affected individual.

Scadding commented that, historically, knowledge about diseases typically proceeds from clinical-description to morbid anatomy to etiology. Certainly his observation seems to be correct when applied to the history of paresis. He argued that any of these approaches to characterizing a disease are appropriate. That is, a disease can be defined in terms of a clinical syndrome; or it can be defined by some associated morbid anatomy; or it can be defined through a recognition of its etiological cause.

The third point to note about Scadding's definition is its emphasis on norms, in that disease refers to an abnormality. To be a disease, the condition must refer to phenomena that are statistically deviant. For instance, most of us have various types of bacteria that normally reside in our intestines and which are important in the digestive process. The presence of these bacteria do not define a disease. The effects of these bacteria are normative. In fact, individuals without these bacteria have abnormal digestive processes.

Finally, the definition ends with the term "biological disadvantage." Scadding introduced this term because he recognized that not all nonnormative aspects of human structure and functioning should be called diseases. For instance, some individuals produce an abnormal amount of ear wax. However, this should not define a disease unless there is some biological disadvantage associated with this condition. Although the term biological disadvantage is not more precisely specified, its general meaning seems clear: syphilis and diabetes place an individual at biological disadvantage since both can lead to death if untreated.

In 1979, Scadding and two Canadian authors (Campbell, Scadding and Roberts, 1979) extended their ideas about disease by studying what physicians and nonphysicians meant by the concept of disease. They published a survey that they had conducted regarding the meaning of disease. To conduct their survey, these authors read a list of possible diseases to four groups of individuals: (i) a group of medical faculty, (ii) a group of nonmedical faculty, (iii) a sample of general practice physicians, and (iv) a sample of youth in British and Canadian schools. The subjects in this study were asked to note whether the terms being read aloud referred to diseases or not. In addition, the subjects were asked to assign degree of confidence ratings to their decisions.

At the top of the list of conditions that were viewed as diseases are infections (malaria, tuberculosis, syphilis, measles). Virtually everyone in the four groups, whether physicians or nonphysicians, agreed that these terms referred to diseases. Syphilis, for instance, was considered a disease by over 90% of the subjects in all groups.

At the bottom of the list were concepts that were not considered diseases by these subjects. Two terms that were seen as referring to diseases by less than 30% of all four groups were drowning and starvation. Many of the terms at the bottom of Scadding's list might be described as injuries, i.e., traumas that affect bodily functioning and that were caused by identifiable external events such as a car accident (e.g., skull fracture) or ingestion of a substance (e.g. barbituate overdose, poisoning).

The psychiatric concepts in the list (schizophrenia, depression, and alcoholism) were ranked in the middle. There was considerable variance among the four groups regarding whether these concepts referred to diseases. For instance, faculty of medical schools rated these three concepts in the following order: schizophrenia (78%), depression (65%), and alcoholism (62%). Children in secondary schools had quite different impressions of what is considered to be a disease: alcoholism (76%), schizophrenia (51%) and depression (23%).

One factor that had a large influence on whether a term referred to a disease concerned the role of a physician in the diagnosis or treatment of the disorder. Malaria and syphilis require a doctor to diagnose and treat. In contrast, starvation can be identified and treated by nonmedical individuals. The latter is also true of acne and hemorrhoids, although the intervention of physicians can prove useful for both. Consistent with this view, acne and hemorrhoids were ranked in the middle of the list. The potential role of nonphysicians in the treatment of mental disorders may also account for the occurrence of schizophrenia, depression and alcoholism in the middle of the same list. Scadding et al (1979, p. 760) concluded their paper with the following interesting comment:

> Most people without medical training seem to think of a disease as an agent causing illness. The common concept of "disease" is essentialist: diseases exist, each causing a particular sort of illness. Doctors tend to adopt a more nominalist position, but they obviously retain remnants of belief in the real existence of diseases.

When viewed from this dualism of an essentialist vs. a nominalist perspective, Scadding had started his definitional attempts from an essentialist perspective but, by the time of his last writings on the topic, he was suggesting that a nominalist view was preferred. Interestingly, the writings of a prominent British psychiatrist, Kendell, who has also tried to solve this issue, have followed the same progression. His ideas shifted from a paper trying to settle on an essentialist meaning of disease (Kendell, 1976) to a skeptical discussion of how the disease model fails to explain alcoholism (Kendell, 1979) to a nominalist view (Kendell, 1986).

Because this nominalism vs. essentialism dualism is so important, the approach of Wulff, Pedersen, and Rosenberg (1986) is discussed briefly. To understand the dualism, Wulff et al. discussed possible ways to classify defective grandfather clocks as an example.

Suppose that one examines how people who work in a repair shop might classify clocks. The receptionist, who knows very little about the workings of the clocks, might classify them descriptively. Thus, some clocks would be placed together because they do not work after being wound; others have broken faces, arms or other parts; and still others do not keep time accurately. Another person who might classify the grandfather clocks would be the bookkeeper of the shop. This individual might classify the clocks according to the manufacturer and cost of the clock. A third person who might classify the clocks is the repairman. He might organize clocks anatomically into those with accumulated dirt impeding their normal functioning, those needing replacement parts, and those with weighting mechanisms that have become unbalanced. Finally, the owner of the repair shop, when reporting back to various manufacturers about the causes of clock malfunctions, might classify the clocks etiologically. That is, she might report about clocks that have had little care, clocks that become worn over various time intervals of ownership, and clocks that developed problems after being moved or damaged.

Which of these classifications—descriptive, cost oriented, anatomical, or etiological—is the true or best classification of defective grandfather clocks? From the nominalist perspective, none of these classifications is inherently the best. Each of these classifications is imposed by the needs of the particular individual using the classification. Each classification serves a function. For any particular function, one classificatory system may be preferable. But none of these is the true classification of defective clocks.

Notice that this apocryphal classification of defective clocks is analogous to the approaches to defining disease suggested by Scadding: clinical-descriptive, morbid anatomical and etiological. The cost oriented classification was simply added as an analogy to how medical classifications are used by the insurance industry in the USA.

Wulff's defective clock analogy was borrowed from the British philosopher, John Locke. Locke had argued that classificatory systems are inherently nominalist, even though the ultimate goal is often essentialist:

> Therefore we in vain pretend to rank things in sorts, and dispose them into certain classes, under names, by their *real essences*, that are so far from our discovery or comprehension. (Wulff et al., 1986, p. 75)

In this regard, it is interesting to contrast Locke's view of classification to those of his physician friend, Thomas Sydenham. Believing in an essentialist view of disease, Sydenham made the following statement which has been quoted repeatedly since then:

> Nature, in the production of disease, is uniform and consistent ... The selfsame phenomena that you observe in the sickness of a Socrates you would observe in the sickness of a simpleton.

In other words, diseases do exist. They do have an essence. It is the business of medical research to discover what these essences are. It was the belief in this essentialist perspective that led nineteenth century researchers to solve the etiological issues associated with dementia paralytica.

Scadding and Wulff et al. warned about the dangers of essentialist thinking when applied to disease. For instance, Scadding noted that often we mistake the disease for the cause of the disease. Noguchi and Moore (Quetel, 1990) discovered the syphilitic bacilli in the brains of individuals with paresis. Hence, we might say that paresis occurs when syphilis invades the central nervous system. But the last sentence is misleading. Syphilis is not an organism. The bacteria, *Treponema pallidum*, is an organism and it could be said to invade the central nervous system. But even if this bacteria were present in the brain of an individual, that presence does not mean that the individual has paresis. To have paresis the individual must manifest the characteristic symptoms and anatomical changes associated with paresis.

Wulff et al. end their discussion of nominalism vs. essentialism with the following statement:

> The philosophical problem which underlies the discussion in this chapter is the age-old dispute about universals, and we have tried to navigate between the Scylla of essentialism (or Platonism) and the Charybdis of extreme nominalism. Essentialism underlines correctly that any classification of natural phenomena must reflect the realities of nature, but it ignores the fact that classifications also depend on our choice of criteria and that this choice reflects our practical interests and the extent of our knowledge. Nominalism, on the other hand, stresses correctly the human factor, but the extreme nominalist overlooks that classifications are not arbitrary but must be molded on reality as it is. (Wulff et al., 1986, pp. 87–88)

As mentioned earlier, defining the concepts of "disease" and/or "disorder" raise complicated issues, and the preceding discussion does not adequately cover the literature. One American author, in particular, has attracted substantial attention in the 1990s for his writings on this issue. Wakefield (1992, 1993) initially addressed this issue by providing a detailed critique of the definition of mental disorder that appeared in the *DSM-III*. Following this seminal paper, other theoretical papers (Wakefield, 1997a, 1997b) proposed a "harmful dysfunction" view of how to define mental disorders. A special section of the *Journal of Abnormal Psychology* has been devoted to a discussion of Wakefield's ideas .

Besides Wakefield's writings, there are other important discussions of this definitional issue including an overview by Reznek (1987), a book by Wing (1978), and an edited book on philosophical issues associated with classification (Sadler, Wiggins & Schwartz, 1994).

4.03.9.3 Two Views of a Hierarchical System of Diagnostic Concepts

Categories in the classification of mental disorders are organized hierarchically. This structural arrangement is commonly recognized but, since the publication of the *DSM-III*, two different views about this hierarchical structure have been discussed. Since these two views are often confused, the next section briefly discussed them.

The first approach to the meaning of hierarchy is nested set approach. Consider, for instance, the *DSM-II* classification of mental disorders. In this system, there are two broad categories of disorders: (I) psychotic disorders and (II) nonpsychotic disorders. The psychotic disorders are further subdivided into (I.A) the organic disorders and (I.B) the nonorganic disorders. The nonorganic psychotic disorders in the *DSM-II* were subdivided into three categories: (I.B.1) schizophrenic disorders, (I.B.2) major affective disorders, and (I.B.3) paranoid disorders. Then the schizophrenic disorders were subdivided into various subtypes: (I.B.1.a) simple type, (I.B.1.b) hebephrenic type, (I.B.1.c) catatonic type, and so on. Notice that this organization of mental disorders has a similar outline to the organization of categories in the biological classification. Any patient, for instance, who would be diagnosed as being hebephrenic, would also be considered as having schizophrenia disorder (the next highest, inclusive category) as well as having a psychotic disorder (an even higher level, inclusive category). Thus, this approach to hierarchy is called a nested set approach because the categories low in the system refer to sets of patients that are included (nested) in higher order categories. This approach parallels the classification of biological organisms in which any animal who is a member of the species *Felis catus* (housecat) is also member of the genus *Felis* (cats) and a member of an even higher order category of *Mammalia* (mammal).

The other approach to hierarchy is called a pecking order view. This view can be best understood by making analogy to the hierarchical organization of rank among military officers. A colonel is higher in rank than a major who in turn is higher in rank than a lieutenant. In this pecking order structure, a colonel can give orders to a lieutenant, but a lieutenant cannot issue orders to a colonel. Thus, the pecking order in military rank concerns lines of authority. A colonel has authority over a lieutenant. Notice, however, that there is no membership nesting in these categories. If a particular individual is a lieutenant, then that individual is not a colonel even though a colonel is higher in the hierarchy than a lieutenant.

To understand how this analogy to the hierarchical arrangement of military rank can be applied to psychiatric classification, consider the following order of general mental disorders:

organic mental disorders
schizophrenic disorders
affective disorders
anxiety disorders
personality disorders.

In terms of the pecking order meaning of hierarchy, this order means that disorders higher in this order should be diagnosed over disorders lower in the hierarchy. Thus, in terms of standard diagnostic practice, the presence of organic mental disorders should be ruled out first, then the schizophrenic disorders, then affective disorders, etc. This principle of diagnostic precedence is analogous to the authority relationship among different levels of rank in the military.

Notice that the pecking order relationship among these five general mental disorders also carries another implication. If a patient has an organic mental disorder, the patient can (and often does) have the symptoms associated with disorders that are lower in the hierarchy. Thus, a patient with Alzheimer's disease can develop hallucinations like a schizophrenic, can have marked sleep disturbance like someone who is depressed, can develop a fear of leaving the house like someone with anxiety disorder, and show the rigidity and need to be controlled like someone with an obsessive-compulsive personality disorder. However, a patient with anxiety disorder such as agoraphobia should not show the disturbed memory patterns and disorientation of a patient with an organic mental disorder. The important point to note is that disorders placed higher in this pecking order view of hierarchy can explain any of the symptoms of disorders lower in the hierarchy; however, the reverse should not occur. There should be symptoms that will be manifest in patients with schizophrenia that will not occur in patients with personality disorders.

The pecking order approach to the hierarchical arrangement of mental disorder categories was popularized by Foulds and Bedford (1975). The specifics of their approach to the classification of mental disorders differs from that presented above, but the general outline is the same. An important corollary to this pecking order view of the hierarchical arrangement among mental disorder categories is that this view suggests that there will be a strong severity dimension in any descriptive approach to the classification of these disorders. Mental disorders higher in this system will be associated with many more symptoms than are mental disorders lower in this system. Descriptive studies of psychopathology have repeatedly found a strong severity dimension that the pecking order view would predict.

4.03.9.4 Problem of Diagnostic Overlap/Comorbidity

When discussing the categorical model of classification, one of the tenets that was attributed to the model stated: "In the borderline areas where categories may overlap, the number of overlapping patients should be relatively small." Diagnostic overlap refers to the relative percentage of patients with one diagnosis who also meet the criteria for another diagnosis. As the tenet above states, some diagnostic overlap is expected. But the relative amount of overlap should be small.

One terminological note should be made before proceeding. The literature on this issue is grouped under the general heading of comorbidity. This term is from the medical literature, because it is well recognized that some medical disorders tend to go together. For instance, individuals who develop AIDS are relatively likely to develop yeast infections, sarcomas, and other disorders because of their compromised autoimmune system. The term comorbidity refers to the pattern of co-occurrences of these medical disorders. However, because the concept of comorbidity implies the acceptance of a disease model, the preferred term in this chapter will be "diagnostic overlap."

One of the earliest studies that focused on diagnostic overlap was by Barlow, DiNardo, Vermilyea, Vermilyea, and Blanchard (1986).

These investigators reported on 126 patients who were referred for the treatment of anxiety. These patients were administered structured interviews. Of the 126 patients interviewed, 108 were assigned one of seven diagnoses that fit within the anxiety/affective disorder spectrum. Of these 108 patients 65% were given at least one additional diagnosis. This is a high level of diagostic overlap and apparently was much higher than these researchers had expected *a priori*.

A large number of other empirical studies have confirmed the high levels of diagnostic overlap using the *DSM-III* and subsequent classifications. Many of these studies are discussed in an excellent review by Clark, Watson, and Reynolds (1995). Examples of the results found in their review are listed below. For example, these reviewers noted one study of personality disorder diagnoses in a state hospital population that found that these patients met the diagnostic criteria for an average of 3.75 Axis II disorders. In addition to the personality disorders, the depressive disorders also have striking overlap with many other disorders. For instance, over half of the patients with major depressive disorder as well as patients with dysthymic disorder were found to have at least one co-occuring mental disorder. Depression shows significant overlap even with disorders that one might not expect overlap. For instance, a sample of antisocial personality disorder patients showed that one-third of these individuals also had a depressive diagnosis (Dinwiddie & Reich, 1993). These antisocial patients, less surprisingly, also had high rates of alcoholism (76%) and other substance use (63%). Even broad epidemiological studies on normal community samples show high rates of diagnostic overlap. Clark et al. reported that, in two national studies, over half of the individuals who had one mental disorder diagnosis had at least one more diagnosis. In some samples, the rate of diagnostic overlap is even higher. For instance, a study of suicidal patients showed that these individuals averaged about four mental disorders (Rudd, Dahm, & Rajab, 1993).

Together, these and many other studies suggest that the number of overlapping patients among mental disorder diagnoses is not small at all. Instead, diagnostic overlap is a standardly occurring phenomenon. Blashfield, McElroy, Pfohl, and Blum (1994) studied 151 patients who had been administered a structured interview to assess personality disorders. In this sample, only 24% of the patients met the criteria for one and only one personality disorder. Exactly the same percentage met the diagnostic criteria for at least four personality disorders, with 6% meeting the criteria for six of the eleven *DSM-III-R* personality disorders! When Blashfield et al. attempted to identify prototypic patients (i.e., individuals who met at least eight of the diagnostic criteria for a specific disorder), they found that only 15% of the patients would qualify as prototypic. However, most of these individuals also satisfied the diagnostic criteria for other disorders. When a prototypic patient was defined as an individual with eight or more criteria for a personality disorder and the lack of an additional personality diagnosis, only 1% of the patients were prototypes. In effect, patients with mixed symptom patterns are much more typical than are patients who represent relatively pure forms of a disorder.

Clark, Watson and Reynolds (1995) suggested that there are three related issues associated with the problem of diagnostic overlap. The first issue concerns the hierarchical organization of categories. As discussed earlier, one view of hierarchy is a pecking order approach. This view was implicitly adopted by the *DSM-III* because a number of exclusion rules were included in the diagnostic criteria for different disorders, so that a lower diagnosis would not be made if a higher order diagnosis was possible. However, research on the exclusionary criteria suggested that these criteria were arbitrary. Exclusionary criteria were mostly deleted in the *DSM-III-R* and the *DSM-IV*.

The second issue associated with the diagnostic overlap issue concerns the heterogeneity with diagnostic categories. In effect, the extensive diagnostic overlap suggests that the definitions of the various mental disorders are too broad and inclusive. Evidence of excessive heterogeneity comes from other sources, according to Clark et al. For instance, direct studies of the variability in symptom patterns have shown high levels of variability within disorders such as schizophrenia, depression, eating disorders and anxiety disorders. Another line of evidence of heterogeneity is the frequency with which mixed or atypical diagnoses are used. For instance, Mezzich, Fabrega, Coffman, and Haley (1989) found that the majority of patients with a dissociative disorder fit the criteria for an atypical dissociative disorder.

The third issue associated with the comorbidity finding is the increasing support associated with replacing the categorical approach to classification with a dimensional view. In the discussion of these two models, it was noted that the dimensional model is the simpler of the two. Unless there is clear evidence of the existence of discrete categories, a dimensional approach is the more parsimonious.

A number of researchers, when confronted with high rates of diagnostic overlap, have suggested that a dimensional model should be used. For instance, in the area of the personality disorders where some of the highest rates of diagnostic overlap have been found, interest in a "Big Five" dimensional approach to the personality disorders has been attracting increasing support. Another example in which a dimensional model is gaining popularity is in the subclassification of schizophrenia. The classic Kraepelinian subtypes do not generate sufficiently homogeneous categories. Various dimensional schemes (process–reactive, paranoid–nonparanoid, positive vs. negative symptoms) have more empirical support than the use of categorical subtypes.

4.03.10 CONCLUDING COMMENTS

This chapter provides a rather simplified overview of the issues associated with the classification of psychopathology. It attempts to help the reader gain a better understanding of classification by starting with a reasonably detailed history of classificatory systems, and thereby give some idea how many of the features of contemporary classificatory systems have evolved. The text also presents a succinct and readable presentation of four issues that currently attract a reasonable degree of attention in the literature. However, justice has not been done to many of the other complex issues that face both clinicians and scientists interested in classification, such as whether to use semistructured interviews as the "gold standard" for measurement (Mezzich, 1984), the role of values in the diagnostic practice of mental health professionals, whether or not certain mental disorders are sexually or racially biased (Busfield, 1996; Nuckolls, 1992; Widom, 1984), the relevance of life-span measures of psychopathology (Roff & Ricks, 1970), and the problem of focusing on the individual patient as the basic unit of psychopathology (as opposed to families or systems or interpersonal relationship patterns) (Clarkin & Miklowitz, 1997; Francis, Clarkin & Ross, 1997; Williams, 1997)

Like any general topic, the classification of psychopathology becomes a very complex topic when analyzed in detail.

> Perhaps I believe that the world can get forward most by clearer and clearer definitions of fundamentals. Accordingly I propose to stick to the tasks of nomenclature and terminology, unpopular and ridicule-provoking though they may be. (Southard, as quoted by Menninger, 1963, p. 3)

4.04.1 PURPOSE OF THE CLINICAL INTERVIEW

The clinical interview is extremely important as a diagnostic tool in the assessment and treatment of patients. Clinicians who do thorough and competent interviews have a much better understanding of the developmental course of symptoms presented by the patient. Indeed, before there were any personality inventories, before the Rorschach and one-way mirror behavioral observation, there was the clinical interview. The purpose of the clinical interview is to gain sufficient information from the informant or informants to formulate a diagnosis, assess the individual's strengths and liabilities, assess the developmental and contextual factors that influence the presenting concerns, and to allow planning for any interventions to follow. The interview is in many instances the ultimate clinical tool, and effective interviewing must be an integral part of any clinician's professional abilities. Although the clinical interview is used primarily to gather information for clinical evaluation or psychotherapeutic treatment, it can also serve the purpose of preparing the patient for therapy, and less frequently the interview process itself provides some relief from psychological distress. The interview may be performed in many different settings: outpatient private practice, community mental health center, psychiatric hospital, prison, emergency or medical hospital room, school, and others.

While the amount of time devoted to the interview, the setting, and the purposes may vary, the features of an effective clinical interview remain the same. When completed, the interviewer has created a relatively comprehensive portrait of the patient that can be communicated readily to others and will provide the basis for making important judgments about the subject of the interview. The relative importance of various symptoms or concerns should be established, along with an estimate of the individual's overall functioning. The relative importance of various symptoms or concerns should be established, and some estimate of the individual's responses in a variety of settings can be made with an acceptable degree of validity. These features can be said to be a part of any clinical interview. Some specific purposes of the interview are described next, along with suggestions about different approaches and emphases the clinician may be required to take.

4.04.1.1 Gathering Information for Assessment and Treatment

The most common purposes of the clinical interview are to gather information to establish a diagnosis, evaluate mental status and historical data that impact upon the individual, and provide a full understanding of the important personality, biological, and environmental variables that have brought the patient to this point. All treatment planning begins with some type of formal or informal evaluation. The clinical interview is the most effective way to gain an understanding of the current functioning and the difficulties faced by the patient, and is a necessary adjunct to the data gathered from other assessment approaches. In the clinical interview, the clinician inquires directly and in a focused manner about the patient's development, adaptation, and current difficulties. When the interview is part of a comprehensive evaluation, some features may be emphasized as a result of the specific referral reason that would not be as prominent in the interview conducted for psychotherapy treatment planning. As an example, the interview conducted for an initial psychoeducational evaluation of an elementary grade school child to determine reasons for school failure is likely to entail considerable emphasis upon academic and learning history and the involvement of one or more of the child's teachers as collateral informants. If the same child were to present later for psychotherapeutic interventions to address the depression and oppositional behaviour problems identified by previous evaluation to be the cause of his academic failure, the interviewer would likely spend more time and effort in determining family interactions, parenting skills, and social supports.

4.04.1.2 Establishing Rapport for Assessment and Treatment

One function of the clinical interview is to prepare the patient for the clinical interventions that follow, including additional formal assessment procedures. In order to obtain valid psychometric data, the patient must be adequately cooperative and invested in the testing process. The interview can help the clinician achieve this end by providing a sense of professional intimacy and a feeling of compassion and interest in the patient's well-being. Thus prepared, the respondent is more willing to give themself over to the process, and to perceive it as being something that will provide them with some beneficial outcome.

4.04.1.3 Interpersonal Style/Skills of the Interviewer

While the basic purpose of gathering relatively concrete information may be accomplished by individuals with a minimum of training and sensitivity, there are a number of personal qualities that tend to improve the quality of information gained and to result in a more helpful and pleasant experience on the part of the informant. Chief among these is the quality of empathy, which must be readily recognized by the informant through subtle and overt communications from the interviewer.

Empathy means identifying with and understanding someone else's feelings, motives, or word view. It means entering the private perceptual world of another person and being at home in it—to be sensitive to what they feel (Egan, 1994; Luborsky, 1996). An intellectual understanding of empathy, however, does not provide one with the interpersonal skills and experience that result in the ability to truly resonate to the informant's experience and to respond in ways that will ease the flow of information of a personal and often sensitive nature. The skill and art of attuning oneself not only to the overt communications of the patient, but also to the underlying feelings and meanings, must become a continuing focus of attention for the interviewing clinician. While much of this process is not fully accessible to conscious awareness, there are some components that lend themselves readily to examination and modification. For example, the interviewer's responses that communicate to the informant negative value judgments are perhaps more easily modified.

Although the mental health fields and their practitioners have often been vilified for their purported moral relativism, no reasonable clinician would believe himself or herself to be free of individual prejudices and deeply-held convictions regarding right and wrong. These values are a part of each person, and to truly expunge them would result in an insipid and ineffective shell of a human being. The relevance to a discussion of clinical interviewing is this: the effective interviewer takes care to be aware of his or her own expectations and biases regarding human behaviour and strives to avoid making explicit negative judgments of the informant in order to provide a comfortable and supportive environment during the interview. This skill can be and is developed and improved through careful attention to the process, internal changes within the interviewer during the interaction, and by effective supervision and review of actual interviews with other clinicians.

Often such judgments can be communicated to the respondent with no more than a change in facial expression or in a shift in questioning. Specific wording and follow-up questions sometimes can have the effect of casting a chill upon the interview process. For example, the interviewer who learns the informant is homosexual and then avoids asking questions about sexual functioning and current relationships readily communicates their discomfort with an important aspect of the informant's personality. The effective interviewer does not perfect an unexpressive mask, but does develop the ability to decrease the immediate translation of visceral responses into explicit behaviours during the interview. Introspection about areas that increase the clinician's anxiety and honest confrontation about discriminatory beliefs are necessary if one is to perform clinical tasks competently and ethically.

4.04.1.4 Structuring the Interview

As with any therapeutic or evaluative intervention, the setting and structure of the interview have a significant effect on the outcome of the interaction. Because the actual face-to-face time spent with patients must be as productive and positive as possible, the clinician should take care to prepare for the clinical interview prior to contact. While the goals of the interview may vary somewhat as discussed previously, many factors common to all clinical interviews should at least be in one's mind prior to and during the interview.

4.04.1.4.1 Setting variables

Some basic attention should be given to simple environmental factors when preparing for the interview. Although many fruitful interviews have been conducted with patients, families, and other sources under conditions that might be charitably described as less-than-optimal, doing so in a comfortable and soothing environment will often add to an informant's ease in discussing delicate and/or emotionally charged matters. Seating accommodations should be given consideration, as hard, uncomfortable, or rickety, precarious seats can add a tinge of anxiety or discomfort to the gestalt of the interview process and thus to the evaluation and/or treatment that follows the interview. It should go without saying that the space being used for the clinical interview should be held relatively inviolate from intrusions, including external noises and conversation to the degree possible. While most people are able to tolerate minor interruptions such as a ringing telephone, having another clinician open the door while your patient is tearfully recounting a past trauma is likely to be somewhat harmful to the tentative alliance you are developing. Therefore, if you work in a setting with multiple users you will do well to take precautions to avoid such disruptions. A white-sound generator can help decrease the penetration of external sounds and add somewhat to the intimacy of the interaction. Throughout the interview the clinician will be carefully observing the behaviours of the subject, noting congruencies and incongruencies, attending to shifts in voice and posture. One sometimes overlooked source of information that may add to the interview process is that of behavioral observations made while the patient and collaterals are in the waiting area of the clinic or office. Often it is possible to observe interactions and general demeanor while you organize paperwork or make other preparations before formally introducing yourself. It may then be helpful to comment during interview on some salient interaction or response. Of course, as has been particularly noted by various custody and forensic evaluators (Bricklin, 1990), the behavior in the waiting room must not be taken as necessarily representative of the person's usual response outside of the clinic. However, one often can observe telling interactional patterns, particularly between parents and children, and this may provide opportunity for addressing problematic areas during the subsequent interview.

4.04.1.4.2 Preparing for the patient

It is common practice now to present the patient with relatively extensive questionnaires or personal history forms prior to the first clinic visit. With this information in hand, the clinician may be able to focus in quickly on the salient symptomatology and current concerns. When available, this information should be used to tailor the interview, allotting time during the face-to-face interview in the most effective manner. If the clinician does choose to utilize such instruments, he or she would be well served to take the time necessary to review the data prior to entering the room with the informant. Watching the professional read and murmur over the forms for minutes while the informant is ignored or asked disconnected questions can be expected to result in a sense of devaluation for the informant. It also gives the impression of disorganization and lack of preparation on the part of the clinician. Neither of these will be helpful in the ensuing interview process.

4.04.1.5 Introductory Remarks

It is helpful to develop a standard approach to the clinical interview, including the introduction and beginning of the interview. One should introduce oneself, and give the informant information about the purpose of the interview and the expected duration. The interviewer's role and title should be clarified, and any supervisory or other training relationship must be disclosed prior to beginning the interview. It is essential that issues of confidentiality be fully addressed, and the informant be given opportunity and encouragement to ask questions about disclosure of information. If any of the data obtained will be shared with other individuals, this must be explained clearly. This is of particular importance in forensic or custody evaluations. When interviewing children and parents, keep in mind the fact that in many jurisdictions the noncustodial parent may retain full rights to examine medical records, including data from the clinical interview. Even if the informant has signed a general disclosure or consent for treatment, it is the clinician's ethical responsibility to review duties to warn and the possible limits on confidentiality. The legal definition of informed consent in many jurisdictions is not necessarily satisfied by the presence of a signature on a form, but rather is established by questioning the informant about their understanding at the time the information was given. The best practice is for the clinician to do their best to make certain that the person with whom they are communicating for professional purposes is fully informed of such issues. In illustration, imagine for a moment being 30 minutes into an interview with a man who informs you very clearly that he intends to use the pistol in his car to shoot his wife when he returns home. If you have fully informed him of the limits of confidentiality, you are in a very distressing situation. If you have not done so, your position is much worse. The growth of managed care and its attendant prospective treatment review process may complicate the ethical duties involved in the clinical interview. As Corcoran and Vandiver (1996) point out, "There can be no doubt that managed care has restricted clients autonomy and interferes with the confidential relationship" (p. 198). During the initial interview and prospective utilization review of a patient whose care is managed by a third (or possibly fourth) party, the clinician may find him or herself in the uncomfortable position of being more the agent of the managed-care organization than the advocate of the patient. In such relationships, it is imperative that the patient be made fully aware at the outset of the interview of the additional limits of confidentiality imposed by the managed-care entity. This may include multiple reviews of the data gained during interview and any subsequent treatment sessions. An additional ethical concern arises in the clinical interview with regard to the establishment of a professional relationship and responsibility for the clinical care of the patient. Does performing the clinical interview and prospective review obligate the clinician to provide service even if the managed-care entity denies authorization? Again, the only way to avoid difficulties, misunderstandings, and possible litigation or board complaints is to be absolutely clear with interviewees and any involved third-party payer about these issues prior to the professional contact. If it is possible that the interviewing clinician will not receive reimbursement from the managed-care company for services, any alternative financial arrangements should also be discussed with the prospective patient before any formal clinical contact. If there are inherent limitations to the number of sessions or type of interventions that are covered by the third-party payer, the potential client should also be made aware of these before ending the interview. Of course, it is possible that no treatment will be necessary; thus it seems sensible to leave discussing the mechanics of paying for it until it is determined to be needed.

4.04.1.6 How to Open the Interview

The best way to open the interview is with a very general, open-ended question about the circumstances that have brought the patient to the interview. Morrison (1995) recommends taking approximately eight to 10 minutes in the typical one-hour interview to allow the respondent to explain in their own words their needs and history. Morrison points out that, among other things, this provides the clinician an opportunity to obtain a true flavor for the respondent's personality and communication style, and to make general observations of behavior, affect, and thought process relatively free from the clinician's direction. An example of an opening question might be "Please tell me about the things that are concerning you most right now" or "I would like for you to tell me what you need some assistance with now" or even "Please give me an idea of how you came to be here today." The amount of information gathered during this portion of the interview will be to some degree dependent upon the respondent's intellectual ability and verbal facility. Many people are characterologically unwilling to self-disclose, even within the confines of the clinical interview, and may require additional urging. The clinician should generally respond to hesitations with supportive restatement of the opening question, or with gentle encouragement and reflection of any apprehension that is detected. If hesitation or lack of content appear to be due to cognitive limitations, disorientation, or distractibility, it may be helpful to ask more direct and close-ended questions based upon previously obtained information or the patient's brief verbalizations. It is generally not desirable to lead the patient any more than necessary, as the more you query the less likely you will be able to distinguish between accurate responses and those that are colored by the demands experienced by the patient. However, in some cases the clinician must take a more directive approach to complete the interview successfully.

The topics to be included in every interview are:

(i) Introduction, purpose of interview, credentials/role of interviewer;
(ii) Confidentiality and exceptions;
(iii) Presenting problems (preferably phrased in general, open-ended manner);
(iv) Mood/Anxiety symptoms;
(v) Impulse control and direct inquiry of suicidal ideation/history;
(vi) Current social, academic, and vocational functioning;
(vii) System of social support;
(viii) Environmental factors, including current basic needs/shelter;
(ix) Developmental factors (especially for children) that may influence symptom presentation;
(x) Medical history, including family health history and previous treatment/hospitalization;
(xi) Substance use;
(xii) Legal involvement and history; and
(xiii) Vegetative symptoms.

4.04.1.7 The Central Portion of the Interview

After the initial introduction, housekeeping, and rapport-building, it is time to focus upon the most salient features of the person being evaluated, and the circumstances that maintain the current dysfunction. Once the presenting problems have been identified and an adequate alliance with the respondent established, the clinician must utilize their knowledge of psychopathology and diagnostic criteria to fully understand and classify the presenting problems, as well as to identify the primary strengths and resources that will be drawn upon by the patient and the professionals involved in subsequent interventions. The central portion of the interview is dedicated to adding to the framework established by queries about the presenting problem. One mistake made by novice (as well as by some more seasoned but overly concrete) interviewers is to rigidly adhere to an interviewing framework, disregarding the natural flow of conversation.

If one is unable to recognize the more subtle verbal and nonverbal messages that should be probed and instead forces one's way forward, the clinician will end up with less information than they should. Thus, it is essential to attend carefully to shifts in mood during the interview, both within the patient and the interviewer.

Luborsky (1996) details the utilization of momentary shifts in mood during a therapy session to focus upon vital underlying thoughts that are salient to the therapeutic issues. The interviewing clinician can also benefit by noticing changes in voice tone, volume, and content of speech. During the central portion of the interview the clinician continues to focus on the problems and possible explanations for present distress. When possible, avoid becoming involved in digressive topics, as some respondents may prefer to spend most of the available time presenting problems that are not central to the services being sought. By the same token, it is the clinician's responsibility to follow any significant leads in the interview, and to be aware of any tendencies on their own part to avoid distressing topics. Experience shows that clinicians tend to be vulnerable to this type of error in particular with regard to sexual functioning, substance use, and racial/ethnic discrimination issues. It may be helpful to keep in mind that while the interview shares many commonalties with social conversation, it is by definition not a run-of-the-mill social interaction. Thus, inhibitions that prevent the interviewer from querying these admittedly uncomfortable topics must be dealt with. Because many clinicians may find themselves having completed much of their formal training without ever overcoming the discomfort experienced when such topics are broached, it may be necessary to practice on colleagues in role-play activity designed to help the clinician become adept at obtaining the necessary information despite initial resistance from within as well as from the respondent. As one of the primary purposes of the clinical interview is accurate diagnosis according to current syndromal criteria from the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*), the clinician must have a solid working knowledge of the criteria for major disorders. Many of the diagnostic categories require precise time qualifiers, so any reports of significant symptoms should be followed by the clinician's efforts to establish their time of onset, duration, and severity. The respondent should be encouraged by the clinician to employ descriptive terms, and to indicate in some way the intensity of the symptoms with a numerical scaling or comparative descriptors.

4.04.1.8 Closing the Interview

As the time for the interview draws to a close, the clinician should consolidate the information gained. It is helpful to review one's notes so that any lingering questions may be answered, and to clarify any dates, names, or other details that may have become confused during the course of the interview. An additional responsibility of the clinician conducting the interview is to assist the informant in achieving closure. Many times the clinical interview results in emotional dilation and some level of cognitive disorganization as distressing events are recalled and exposed to another person. The skilled clinician will continue to structure the interview with reminders about the amount of time remaining, summarizing the information provided, and giving appropriate feedback to the informant regarding what to expect next. Avoid rushing the informant out of the room, but be prepared to set limits about the closing of the interview.

When possible, it is beneficial to give the informant a good idea of your diagnostic formulation, and to outline possible intervention strategies. If this is not possible or appropriate at the close of interview, convey to the informant what steps will be taken to complete the evaluation, or provide the informant with an idea of how the information provided will be utilized. If possible the informant should leave the interview with the feeling that they have been heard, understood, and will be benefiting in some way from having participated.

4.04.1.9 The Collateral Interview

Collateral interviewing refers to any direct interviewing done with persons other than the identified patient. Common collateral individuals who are interviewed in the clinical setting include parents, spouses, siblings, and other close relatives. In the case of children and adolescents, school teachers, administrators, and counselors are also often interviewed directly about the behavior and adaptive functioning of the patient. The same skills used in interviewing the identified patient will be employed in these interviews. Empathy, a lack of criticism, and an appropriate use of humor are just as indispensable in talking with a spouse or school principal as they are with the individual presenting for assessment and/or treatment. In many cases, the collateral interview is conducted because the patient is unable to provide the needed information on their own because of disorganizing pathology or other limiting factors, making a collateral information source even more important. In conducting the collateral interview, one must also determine, to the extent possible, the degree of reliability or weight to place upon the information thus gathered.

The clinician should consider the amount of time the informant has known the patient, and the circumstances under which the patient has been observed by the informant. In the case of the school teacher, beginning with questions regarding the amount of time spent with the patient and the subjects taught provides an opportunity to gather useful information about the school setting. In addition, this allows the clinician to evaluate to some extent the affective responses of the informant toward the patient, for example, excessive anger or frustration on the part of the teacher may point to possible distortions in reporting. It is helpful to probe gently for the teacher's experience level, to avoid being unduly influenced by the observations of one who has relatively little comparative knowledge of normative classroom behavior. Begin by asking how long they have been in this particular school, or teaching this particular grade. If the teacher is special education certified, ask how long they have been certified and in what areas. Usually these queries will be sufficient to obtain a good estimate of the experience base of the teacher, and most will actually respond to the general probes with more than enough information to make appropriate judgments.

In the case of the parent interview, take care to establish current custody arrangements and responsibilities as clearly as possible. Depending upon the jurisdiction in which the clinician works, noncustodial parents may not have the right to seek mental health services for the child. It is the clinician's responsibility to be aware of all the legal constraints on service, as well as the ethical duties peculiar to working with children or others who are unable to consent to treatment legally. Be cautious about taking the word of one parent involved in a visitation or custody dispute who reports that the other parent has no interest in the child, or that the other parent would be completely uninterested in assisting in assessment or treatment for the child. Experience indicates that while this may be true in some cases, this attempt to shut the other parent out of clinical work may result in significant distortion of the presenting facts, and can hamper effective work with the child. Thus, if the parent bringing the child for services indicates that their (ex)spouse will not participate in the interview, go ahead and obtain consent from the present parent to contact the reportedly uninvolved parent. This action would only be contraindicated if the clinician has convincing evidence that contacting the other parent would present a significant danger to the patient.

4.04.2 DEVELOPMENTAL CONSIDERATIONS IN INTERVIEWING

4.04.2.1 Interviewing Children (Preschool Age through Older Elementary)

Because children are usually brought into the clinic setting by their parents, clinicians typically schedule an interview with the parents to obtain information about current concerns and past history. Parents are in a unique position to provide a chronology of significant events in the child's life, leading up to the present concerns and reasons for referral. Often collateral interviews will be scheduled with others who play a significant role in the child's life, such as grandparents, teachers, day care providers, etc. Indeed, some diagnoses (such as attention deficit hyperactivity disorder [ADHD]) require that symptoms be documented across at least two settings, and it is helpful to have informants from settings such as school to add to the history provided by parents. One should not limit interviewing to only the adults who are significant in the child's life, however. To do so would create a risk of overlooking important information that could be obtained from the child directly about the child's perceived fears, anxieties, mood, and critical events in the child's world. The child's perspective is often overlooked in situations where the child is not articulate about feelings or is immature in language development. It is necessary for the clinician to develop skill in obtaining interview information from children even in these circumstances. An excellent resource for interviewing or observing children, including infants, can be found in Sattler (1998, pp. 96–132).

4.04.2.2 Interviewing Parents

The purpose of the interview with parents is similar to that discussed earlier in the chapter, in that the clinician attempts to clarify the reasons for concern, identify strengths and weaknesses that moderate the presenting problems in the child, and obtain information that could assist with treatment planning. However, there are important ecological variables that are salient for children and should be addressed in the interview. These include placing the child's current and past problems into a social and developmental context, assessing possible risk and resilience factors that may relate to the child's problems, and assessing the consequences or developmental impact of the child's problems on their future development.

4.04.2.3 Social Context

Schroeder and Gordon (1993) outlined several steps in assessing the problems of young children, including clarifying the referral questions and determining the social context of the problem. Parents often present to clinicians feeling anxiety and/or frustration about their child's problems. This may lead to emotionally-laden, imprecise descriptions of behavior (e.g., "He never minds!" or "She is always disrespectful to her parents!"). The first task in the interview is to help parents define the specific behaviors that cause concern, and to obtain information about the frequency, intensity, and nature of the problem. For instance, a three-year-old child who displays temper tantrums once per week may be of mild concern, but, one who has tantrums three to five times per day would be of much greater concern. The intensity of the child's problems might be gauged by the degree of distress caused to the child or the disruption to typical family activities. For instance, tantrums that occur occasionally at home may cause less distress than if they occur with regularity at church, school, or in other public places. Finally, the nature of the child's problems will be an indicator of severity. Children who engage in cruelty to animals or other people, who are destructive, or who engage in a pattern of fire-setting behavior with the intent to destroy property are of more concern than those who have less serious oppositional and defiant symptoms. As clinicians interview parents about the specific behaviors of concern, important information about the frequency, nature, and severity of the problems can be assessed.

The social context is best assessed by asking simple questions such as, "Who is concerned about the child?," "Why is this person concerned?," and "Why is this person concerned now vs. some other time?" (Schroeder & Gordon, 1993). Although parents or teachers may refer children for assessment or treatment, this does not mean that the child necessarily has a problem that needs treatment. A teacher who refers several active children from a first grade class may be feeling overwhelmed by the sheer number of active children in the class at one time, although a given child's behavior may not be severe enough to warrant a diagnosis of ADHD. Rutter and Schroeder (1981) provided a case of example of a mother who presented with concerns about her daughter occasionally masturbating while watching television. In an attempt to determine why this mother was concerned and the best approach to intervention, the clinician asked about the mother's perception of what this behavior means. The mother responded by saying that she knew her daughter was at a developmental age when exploring her body was normal, and she knew that nothing bad would happen (e.g., such as growing hair on the palms of her hands) as a result of masturbation. The additional question ('Why is the mother concerned now vs. any other time?") yielded the most salient information about the mother's concerns. The mother revealed that her mother-in-law was coming for a visit the next week, and she was concerned that this relative would have a negative reaction to seeing her granddaughter masturbate. The intervention was simplified by understanding the true reason for the mother's concern. The clinician recommended that the mother provide rules about when and where it was acceptable to masturbate (e.g., when her daughter was alone, in her bedroom, or in the bathroom) and institute a behavioral reward system for remembering not to masturbate while watching television.

Other social contextual information can be obtained about family status (who is living in the home), recent transitions (moves, job changes, births, recent deaths, or illnesses of significant family members), and other family stresses (marital problems, financial stresses, etc.). The presence of persons who are supportive to the child, or who may provide a buffer in the face of other stresses, is important. The literature on resilience is replete with examples of children who have lived with adversity but have developed and functioned normally due to protective factors in their social history (Routh, 1985). The interview with parents also provides an opportunity for assessing possible psychopathology in the parents, such as significant depressive or anxiety symptoms; problems with anger management and self-control, as is often seen in abusive parents; substance abuse problems that may lead to parental instability or neglect; or problems with reality testing, as in schizophrenia. One mother, for example, described her 14-year-old son as being afraid of the dark and reporting seeing ghosts at night. This was viewed by the clinician as an example of a fear that was developmentally inappropriate for a 14-year-old; it also raised questions about possible hallucinations. The context became more clear when the mother revealed that she saw nothing inappropriate about this behavior. The mother reported that she, too, needed to sleep with a light on due to her fear of the dark, and that she also imagined seeing ghosts in her bedroom. This mother reported that she and her son had many discussions about their mutual fears. The context of the son's fears was changed by the mother's revelation, and the clinician decided to include a more thorough interview regarding the mother's mental status in this case. Even when no concerns about parental psychopathology exist, parental stress levels and affect must be considered when interpreting their reports about child behavior. A parent who is calm and rational in providing a history of their child's behavior may be viewed as more objective than a parent who is extremely upset, tearful, or angry and uses exaggerated descriptors of the child's behavior.

4.04.2.4 Developmental Context

Developmental context provides an essential lens from which to view children's behavior, allowing the clinician to evaluate the child's behavior relative to that of other children of the same chronological and/or mental age. For instance, enuresis may not be unusual in a four-year-old, but would be of concern in a 14-year-old. Likewise, enuresis may not be unusual in a six-year-old youngster with a moderate degree of mental retardation. Some behavioral problems of young children are transient, reflecting their responses to normative developmental challenges (e.g., a five-year-old girl who displays a regression to thumb-sucking and infantile speech patterns following birth of a new sibling). Other problems are more serious and persistent, and suggest risk for later maladjustment. Familiarity with developmental theory and the rich empirical literature in clinical child psychology and developmental psychopathology can provide the clinician with guidance in making these discriminations.

Knowledge of the sequence and transitions in social/emotional development are helpful to the clinician in judging the appropriateness of children's behavior at various ages. For instance, a toddler who has never displayed a strong attachment to a primary caregiver (usually a parent or parents) and who seems to form attachments indiscriminately with others would raise concerns about possible attachment relational problems. A seven-year-old child who cannot delay gratification or consider the feelings of others would be of concern for not having learned appropriate self-control and capacity for emotional empathy that would be expected at that age. Critical developmental tasks for the preschool age child include establishing effective peer relations (e.g., learning to share material resources and adult attention with peers, establishing reciprocal play relationships) and developing flexible self-regulatory skills (e.g., adjusting to the authority of preschool or daycare teachers and classroom routines). In contrast, children in middle to late elementary years (seven to 12 years of age) encounter developmental tasks related to mastery of knowledge and intellectual skills, leading to feelings of productivity and competence. Children with learning disorders or other developmental problems that interfere with academic progress may be at risk for secondary behavioral or emotional problems related to their primary problems with learning during this developmental period. The clinician must tailor the interview to exploration of the child's strengths and weaknesses in the context of appropriate developmental expectations for particular ages.

The newly emerging field of developmental psychopathology has provided a theoretical and empirical base for better understanding the developmental precursors of psychopathology in children, and the impact of this psychopathology on subsequent functioning (cf, Cicchetti & Cohen, 1995a, 1995b). There is a growing body of research addressing risk factors for the onset and continuity of various childhood disorders. For example, Loeber and colleagues have made important contributions to understanding the developmental pathways to childhood disruptive behavior disorders, in which different constellations of risk factors lead to different outcomes. In their longitudinal study of inner city boys at ages seven, 10 and 13, they found that initiation into antisocial behavior was predicted by some factors (e.g., poor parent–child relations, symptoms of physical aggression) that were present across all three ages, while others (e.g., shyness at age seven, depression at age 10) were age specific (Loeber, Stouthamer-Loeber, Van Kammen, & Farrington, 1991). Further, the environments of children who remained antisocial differed from those whose antisocial behavior dropped out; good supervision was more important in helping older children (age 13 at intake) while attitude toward school was more important for the younger children. Studies such as these illustrate the importance of understanding the contextual variables related to parenting style and parent–child relational issues, as well as specific child behaviors, in determining the significance of presenting problems and their possible trajectory over time.

4.04.2.5 Direct Interview of Children

Perhaps the best and most comprehensive resource guide for interviewing children and adolescents who present with a variety of problems is Sattler's (1998) book on clinical and forensic interviewing of children. Basically, the goals of the initial interview of the child depends upon the referral questions as well as the age and verbal ability of the child (Sattler, 1998). When interviewing children and their families the information sought often includes the following:

(i) to obtain informed consent to conduct the interview (for older children) or agreement to be at the interview (for younger children);

(ii) to evaluate the children's understanding of why they are at the interview and how they feel about being at the interview;

(iii) to gather information about the children's perception of the situation;

(iv) to identify antecedent and consequent events related to the children's problems;

(v) to estimate the frequency, magnitude, duration, intensity, and pervasiveness of the children's problems;

(vi) to identify the circumstances in which the problems are most or least likely to occur;

(vii) to identify potentially reinforcing events related to the problems;

(viii) to identify factors associated with the parents, school, and environment that may contribute to the problems;

(ix) to gather information about the children's perceptions of their parents, teachers, peers, and other significant individuals in their lives;

(x) to assess the children's strengths, motivations, and resources for change;

(xi) to evaluate the children's ability and willingness to participate in formal testing;

(xii) to estimate what the children's level of functioning was before an injury; and

(xiii) to discuss the assessment procedures and possible follow-up procedures. (Sattler, p. 98).

A part of the interview process with children includes observation of parent and child and obtaining collateral information from the schools or others if the presenting problem relates to learning or behavior problems outside the home. Recognizing the developmental tasks that children must master at varying ages helps the clinician understand the child's behavior. Thus, a comprehensive, detailed developmental history of the child and family milieu is an integral part in establishing an appropriate treatment.

Clinicians must also consider interviewing the child at some stage during the evaluation process. Very young children may be observed using a free-play setting and using observational guides during the play. The clinician can learn a great deal about the child's energy level, physical appearance, spontaneity, organization, behavior, affect, and attitude through their play and through a diagnostic play interview. School-aged children are able to share thoughts and feelings with the clinician unless they are unusually shy or oppositional (Sattler, 1998). Obviously establishing rapport and maintaining the child's cooperation during the interview is crucial. Kanfer, Eyberg, and Krahn (1992) identified five basic communication techniques that can aid the clinician in attaining rapport and cooperation. First, the clinician can use descriptive statements to describe the clients ongoing behavior, for example, "You're stacking the toys so nice." Second, using reflective statements to mirror the childs statements can be nonthreatening. For example, if the child says she wants to play with blocks the clinician merely reflects "you want to play with the blocks." Third, labeled praise helps the child feel good and feel that the clinician approves of them. Fourth, the clinician must avoid critical statements that suggest disapproval or make the child feel as though they are bad. Finally, open-ended questions avoid yes or no answers and provide opportunities for children to elaborate on their responses (Kanfer et al., 1995).

4.04.2.6 Adolescents

Interpersonal style may play a greater role in good interviewing with this age group than with any other. Adolescents tend to be intensely attuned to any communications that concern their personal appearance, skills, or competence, and the interviewer must avoid at all costs even the hint of condescension. As numerous authors have pointed out, older clinicians tend to identify readily with the parents of adolescents, while younger ones may easily align themselves with the youth. The clinician who remains unaware of their tendencies in this regard runs the risk of making insensitive or intrusive statements that will inhibit rapport rather than increase it. In the first case, the clinician who approaches the adolescent with a parental attitude may unconsciously interact in a way that increases the informant's anxiety, guilt, and hostility. Questions that presuppose information the adolescent has not provided may mirror intrusive interactions with other adults, resulting in defensive efforts and guardedness. Similarly, clinicians who identify easily with the adolescent may also appear "hokey" and insincere when they misuse popular language, or try too hard to relate their own somewhat misty adolescent experiences to those of the youth they are interviewing. These errors result from incautious use of the same techniques that will be necessary for successful adolescent interviewing. That is, to obtain good information and develop adequate rapport, the adolescent must perceive that the clinician is clearly on their side within the boundaries of the relationship. Judicious use of self-disclosure can help the adolescent believe that the interviewer is not attempting to take away from the interaction without reciprocating. Earnest discussion of the limits of confidentiality and the purposes of the interview will help allay some of the suspicions the informant may have about the clinician's role, and will serve to make a distinction between the clinician–informant relationship and those the adolescent has with parents, teachers, parole officers, and other adults.

The adolescent patient presents a number of challenges to the interviewer that are often less present or significant in interactions with both older and younger people. Because of the unique developmental pressures and challenges of adolescence, special care must be taken in the interview to ensure adequate cooperation as well as to make the interview process a helpful one to the patient. It is essential that the interviewing clinician possess a basic knowledge of the common demands and urges present in the adolescent and their family to effectively assess the patient's functioning. Listed next are those tasks commonly believed to be operating in the adolescent period of life according to various developmental theorists (Erikson, 1963; Rae, 1983).

4.04.2.6.1 Separation–individuation

Separation–individuation refers to the need of the adolescent to identify those qualities in themselves that set them apart from their family. Many of the issues bringing adolescents to treatment involve conflicts that are direct results of this process. The adolescent during this time begins testing family boundaries and experimenting with beliefs and behaviors that differ from those held by their caretakers. This process often produces considerable anxiety for all family members, and the adolescent's interpersonal relations may become quite variable. Often, the adolescent moves between the poles of autonomy from, and dependence upon, the family. An important portion of the adolescent interview is that of identifying the severity of the stressors resulting from this natural process.

4.04.2.6.2 Resolving conflict with authority figures

Related to the individuation task is the frequent occurrence of conflict with authority figures outside of the family as well as within. For younger adolescents this involves primarily their teachers and other school personnel, and for later adolescents this includes work supervisors as well. Conflicts with authority figures outside the home often have their roots in greater-than-average difficulties in resolving the family relationship struggles. Thus, when interviewing the adolescent, it is helpful to identify both positive and negative relationships with other adults in their life.

Often classroom performance for the adolescent presenting for services is related strongly to the quality of the relationship with the teacher, so discussion of academic performance (usually a relatively nonthreatening issue in the context of the clinical interview) can elicit useful information about this area of functioning as well. Adolescents, as well as younger children, may readily express relational difficulties in response to the question "Is he/she a good teacher?" This often elicits the adolescent's opinion regarding the desirable qualities in an important adult, and allows the interviewer to follow up with questions regarding the adolescent's ability to recognize their own role in any positive or negative interactions.

4.04.2.6.3 Peer group identification

As adolescence is inarguably a time of shifting focus from family relations to peer relations, it is vital to gather information regarding the patient's friendships and any identification with a social subgroup. Some effective ways of eliciting this information include discussion of music topics, such as taste and dress, that will provide clues to the adolescent's social presentation and degree of inclusion or exclusion from social groups.

To effectively interview adolescents regarding social issues, it is necessary for the clinician to maintain a moderate degree of understanding of popular culture. Thus, one would be well served by making an effort to watch television programming, read magazines, and spend time taking in the various electronic media that are aimed at people in this age group. The interviewer should not attempt to present as an authority on the adolescent's culture, but will benefit from being able to recognize specific music groups, current movies, video games and Internet activities, and other elements that are part of the adolescent's milieu. It is often helpful to enlist adolescents' aid in delineating the social groups present in their school, then ask them to identify the group to which they feel they most belong. This question can usually be asked rather directly, and many teens are pleased by the opportunity to display their understanding of the social complexities in their school.

Follow-up inquiry should establish with whom the adolescent spends most time and how they see themself as fitting into the groups at school. Many youth social strata include a group delineated primarily by drug/alcohol use as well as different groups for aggressive or delinquent behavior that may be gang-affiliated or gang-emulating. Thus, the social categories to which the adolescent assigns themself may also point the interviewer toward necessary inquiries into these possible problem areas as well as providing information about the degree of social integration in the adolescent's life.

4.04.2.6.4 Realistic appraisal and evaluation of self-qualities

As the focus of evaluation or treatment is likely to include assessing and modifying self-image, it is necessary to include questions regarding the ways in which the adolescent views themself. Adolescents generally display both overly optimistic and excessively pessimistic appraisals of personal qualities. One purpose of the interview is to assist in determining when these perceptions area faculty and result in impaired functioning. It is often helpful to present questions about self-image in terms of strengths and liabilities, and to follow up on both. Questions about the adolescent's physical capacities as well as social and emotional abilities are necessary components of the interview. This portion of the interview can be directed toward uncovering problems with perception of body image and behaviors related to physical health. The interviewer should attend carefully to clues that might indicate the need for more focused exploration of possible eating disorders, and to somatic complaints indicative of anxiety or depression.

4.04.2.7 Interviewing Young Adults (18–40 Years)

The psychological distinction between adolescence and young adulthood is frequently blurred, and many of the same traits and problems may be observed in individuals both over and under the chronological age of majority. However, since the age of majority is generally 18 years, a higher proportion of patients over age 18 will be self-referred and hence will present in a more open and cooperative manner than some adolescents. Additionally, young adults are more likely to present with some subjective description of their distress and their situation. Therefore, the client may be more likely to identify a problem area spontaneously. Despite the fact that more patients in this age group may independently seek services, many of the adolescent issues related to establishing an autonomous role-identity may surface in the interactions with the interviewer, especially with the "youngest" adults. Therefore the interviewer may frequently call upon the skills used in interviewing adolescents.

Erikson (1963) identified the primary developmental conflict for the various stages of adulthood, and these stages suggest important interview topics (see Table 1). The primary conflict of young adulthood is intimacy vs. isolation. Consequently, many of the psychological problem areas frequently encountered will revolve around commitment to interpersonal relationships and establishing trust. Establishment of a working relationship with the patient is also affected by these issues.

A relatively greater amount of the interview might be devoted to exploration of existing relationships or those the patient wishes existed. One type of relationship to consider is that with parents and family of origin. Establishing the degree of desired independence continues to be an issue with some young adults. Issues relevant to these ties might be financial (e.g., parents may be paying college expenses), or they may be more interpersonal in nature (e.g., parents controlling social relationships or defining goals for the patient).

Intimate relationships with individuals of the same or opposite sex may also be a source of psychological discomfort and play a part in the development of anxiety disorders or depression. Inquiry about social functioning should include peer relationships, such as partners in love relationships, friends, and acquaintances.

Individuals in the young adult age group generally will have established some degree of independence, and the relative importance of work and employment will be much greater than at younger ages. The interview should therefore include specific inquiry into current job status, job satisfaction, goals, and relationships with co-workers. The further one progresses into this stage, the greater is the importance of establishment of a stable intimate relationship and mutual trust, and the higher the probability that the issue of procreation will arise. Therefore inquiry should include questions about intentions and concerns associated with having children and child rearing and any differences with one's partner about children.

Finally, the initial episodes of many severe psychiatric disorders are most likely to occur within the young adult period. Initial episodes of depression, and post-partum depression, are likely to occur in those affected before they pass through this period (Kaelber, Moul, & Farmer, 1995). Therefore screening for affective disorders should be included in the interview. A

Table 1 Interview topics for each developmental stage.

Young adult	Independence from family, relationships with peers, stable intimate relationships, trust in relationships, establishment of a family, issues related to having and rearing children, education, and career goals.
Middle adult	Achievement of work and family goals, career or family role changes, responsibility for aging parents, death of grandparents and parents, reducing responsibility for children, changes in physical appearance and characteristics, and anticipating retirement.
Older adult	Accepting status of family and career, developing identity as grandparent or "elder advisor," coping with reduced physical capability and/or health changes, specific plans for retirement, loss of siblings, spouse, and friends. Increased reliance on children or caretakers.
Late adult	Coping with deteriorating health, decreased mobility, dependence on caretakers, and anticipation of death.

later section of this chapter deals with interviewing depressed and anxious patients. Additionally, first episodes of schizophrenia or bipolar disorder generally take place in adolescence or young adulthood and the interviewer should be sensitive to symptoms of these disorders.

4.04.2.8 Interviewing Adults in Middle Adulthood (40–60 Years)

Interview techniques need not differ with this age group, but the relevant topics from a developmental perspective are somewhat different (see Table 1). This period encompasses much of the creative and productive portion of the life span in western culture. The emphasis is not on starting, but on completing tasks begun in young adulthood. The focus of individuals at this stage of life is much less on goal setting than on goal attainment. The growth and nurturing of an established family, the attainment of successive career goals, and nurturing of one's parents and grandparents occur in this time span. One's children come into adulthood and begin to establish their identities and families. Inquiry into the relationships with the former and succeeding generations should be made. Towards the middle of this period, individuals are able to anticipate the likelihood of reaching family and career goals, and become aware of the fact that certain goals for themselves and their children may not be met. Biological changes associated with mid-life, which are well-defined for women, but also may be present for men, should be queried since they may be associated with depression or anxiety. Possible mid-life existential crises related to loss should also be assessed. The losses may result from death of parents or grandparents, or changes in roles as parent, spouse, or worker.

4.04.2.9 Interviewing Older Adults (60–70 Years)

For many adults in this age range, the predominant life circumstance deals with additional impending changes in the area of life roles. Retirement usually occurs within this time frame, and inquiries might reveal difficulties in psychological adjustment to one's own retirement or the retirement of a significant other. The frequency of death in the patient's social circle gradually increases, and may include a spouse, close friends, or even an adult child.

Due to the possibility of some early decline in cognitive capacity in this age group, the response to inquiry may be defensiveness and denial. The patient with some early impairment may deny the need for the evaluation, object to questions, and become resentful if the interview serves to demonstrate difficulties with memory. Therefore, it becomes more important to interview a collateral person or include a collateral person in the patient interview. In addition to a spouse or family member, a collateral person to be considered with older adults is an adult caretaker, who may or may not be related to the patient. This may give rise to some special issues of confidentiality.

Attention to the collateral person's nonverbal behavior may sometimes suggest that they are uncomfortable reporting the patient's difficulties, especially in the patient's presence. In such circumstances a separate collateral interview is desirable.

4.04.2.10 Interviewing In Late Adulthood (70 Years–End of Life)

Adults in the latest stages of life have their own unique set of circumstances of which the interviewer must be aware. The losses that may have begun earlier may become more frequent.

Physical changes, often represented by medical problems, may interfere with some life activities, and there may be a need to accept reduced independence. At some point anticipation of the end of life is common. The combination of these forces often lead the elderly to have a perspective on life and the situation giving rise to the interview that differs considerably from younger adults, in that they may be unconcerned and see no need for the evaluation. Often the reasons for the interview are more important to someone else than to the patient. As with children and adolescents, it is more likely that someone other than the client identified the need for and arranged for the mental health contact.

It is also common for the oldest adults to answer questions more slowly, either because of difficulty accessing information or because a more tangential and elaborate route is taken to reach a point in conversation. Patience on the part of the examiner in these situations is important, both for maintaining rapport and to show the proper respect due the patient.

It has been estimated that the incidence of cognitive decline in people over age 65 is 10–20% (Brody, 1982). Estimates are as high as 25% of those 80 years and older (Hooper, 1992). Thus, the likelihood of cognitive impairment is even greater in this age group than those discussed previously. For those with cognitive dysfunction, cooperation may be minimal and denial, and even belligerence, may be present. Again, the availability of a collateral person for interview may be very important, as the patient may not cooperate or may be impaired in their ability to provide information.

4.04.3 INTERVIEWING SPECIAL POPULATIONS OR SPECIFIC DISORDERS

4.04.3.1 Interviewing Depressed Patients

Interviewing depressed adults may require some adjustment in the tempo and the goals of the interview. Due to low energy and psychomotor retardation, it may not be possible to gather all the desired information within the time available. Hence, some prioritization of information is necessary, so that issues such as suicidality, need for hospitalization, and need for referral for medication may be addressed. Beck (1967) and later, Katz, Shaw, Vallis, and Kaiser (1995) pointed out that the interpersonal interaction with the depressed patient may be frustrating for the interviewer, not only due to the slowness mentioned above, but also because of the negative affect and negative tone of information provided.

It is also particularly important with depressed patients, who are prone to hopelessness, to provide encouragement and attempt to impart hope to the patient during the interview. This may be done by recognizing areas of strength, either in terms of personal qualities or successful areas of functioning.

Specific inquiry is necessary to diagnose depression appropriately, and a variety of sources are available to guide this inquiry. Diagnostic criteria for depression are clearly delineated in the *DSM-IV* (American Psychiatric Association [APA], 1994). A number of structured interviews have been developed that may serve as guides for inquiry or provide sample questions. Formal training is required for the reliable use of these interviews for diagnostic purposes. The Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) is a relatively early forerunner of current interviews that slightly preceded the *DSM-III* (APA, 1980), and includes probe questions for depressive symptoms as well as other disorders.

The Structured Clinical Interview for *DSM-III-R* (SCID; Spitzer, Williams, Gibbon, & First, 1992) is a more current instrument with a modular format so that sections for each disorder may be used independently. Table 2 also lists sample questions that might be used to probe for the presence of various depressive symptoms.

4.04.3.2 Interviewing Anxious Patients

The anxious patient may also present some special difficulties during the interview. If the patient is acutely distressed at the time of the interview, as might be true of someone with a generalized anxiety disorder, they may provide a rush of disorganized information so that it may be difficult to obtain a coherent history. Anxiety interferes with attention and concentration, so that repetition may be necessary. Experience has shown that in such a situation, some initial intervention using brief relaxation techniques, is helpful before proceeding with the interview. Anxious patients also frequently seek reassurance that treatment will be effective in reducing their anxiety. It is appropriate to indicate that treatment techniques have been helpful to other anxious patients, and that these techniques will be available to them.

The diagnostic symptoms of various anxiety disorders are identified in *DSM-IV*, and the structured interviews mentioned earlier also provide some guidance for the inquiry for specific anxiety symptoms. In addition to the diagnostic information, it is important to

Table 2 Sample questions for depressive symptoms.

Mood (depressed)	How would you describe your mood? Have you been feeling down or sad much of the time? How much of the time do you feel down or sad?
Mood (irritable)	Have you been more short-tempered than usual for you? Do others say you are more irritable or lose your temper more easily than usual?
Interest and pleasure	Are you as interested as ever in things like your work, hobbies, or sex? Do you continue to enjoy the things you usually like to do, like hobbies, doing things with friends, or your work? Has your interest declined in things which used to be really interesting for you?
Energy/fatigue	Do you have enough energy to do the things you want to do or need to do? Do you have the energy to do the things you find interesting? Do you tire out more easily than usual for you?
Weight loss/gain	Have you gained or lost weight since . . . (specify a time period)? If the patient does not know, you may inquire about whether clothes fit properly, or what others may have said about weight. Insomnia/hypersomnia
Insomnia/hypersomnia	How well are you sleeping? Do you have difficulty getting to sleep? (initial insomnia). Do you awaken frequently during the night and have trouble getting back to sleep? (middle insomnia) Do you awaken too early in the morning? (terminal insomnia)
Psychomotor agitation/retardation	Have other people commented on your being too active or being very slowed down? Are there times when you just can't sit still, when you have to be active, like pacing the floor or something similar? Are there times when you are very slowed down, and can't move as quickly as usual?
Worthlessness/guilt	How do you feel about yourself? Do you think of yourself as worthwhile? Do you often feel guilty or have thoughts of being guilty for something? Is guilt a problem for you?
Concentration/decisiveness	Is it difficult for you to keep your attention on things you are doing? Do you lose track of things, like conversations or things you are working on? Is there a problem with making decisions? Does it seem that your thoughts are slowed down, so it takes a long time to make a decision?
Thoughts of death/suicide	Do you frequently have thoughts of death? Do you think a lot about friends or loved ones who have died? (Inquire if someone close to the patient has recently died or is near death.) Do you sometimes think it would be better if you were dead? Have you thought abut hurting yourself or killing yourself? Have you planned a particular way in which you would kill yourself? What would keep you from killing yourself?

inquire about ways the patient has attempted to cope with the anxiety, and to provide some reinforcement for such efforts.

4.04.4 SUMMARY

The clinical interview provides rich diagnostic information that can aid in the assessment and treatment of patients. Interpersonal style of the clinician interview, structuring the interview, the setting in which the interview takes place, preparing the patient, and the beginning, middle, and ending phases of the interview are discussed. Developmental considerations and suggestions are offered in interviewing children, adolescents, and adults. Sample questions are primarily for interviewing depressed patients.

4.05.1 INTRODUCTION

As early as the 1930s, and certainly by the early 1960s, it was apparent that clinical diagnostic interviews were fallible assessments. Evidence suggested that clinicians frequently arrived at different diagnoses, often agreeing at no more than chance levels (e.g., Beck, Ward, Mendelson, Meck, & Erbaugh, 1962; Matarazzo, 1983; Spitzer & Fleiss, 1974). These findings gave raise to the study of the causes of diagnostic unreliability as well as the development of methods to improve psychiatric diagnosis.

In the first study systematically to examine reasons for diagnostic disagreement, Ward Beck, Mendelson, and Erbaugh (1962) summarized three major sources of disagreement. These were inconsistency on the part of the patient (5% of the disagreements), inconsistency on the part of the diagnostician (32.5%), and inadequacies of the nosology (62.5%). Thus, nearly one-third of the diagnostic disagreements arose from the diagnosticians. Factors associated with differences between diagnosticians included interviewing techniques that led to differences in information obtained, weighing symptoms differently, and differences in how the symptomatology was interpreted (Ward et al., 1962). It is interesting that these problems arose despite methods of study which included the use of experienced psychiatrists, preliminary meetings to review and clarify diagnostic categories, the elaboration of diagnostic descriptions to minimize differences, and the compilation of a list of instructions to guide diagnosis (Beck et al., 1962).

The study of Ward et al. (1962) identified two major sources of disagreement that have been termed "criterion variance" and "information variance" (Endicott & Spitzer, 1978). Criterion variance refers to the errors in diagnostic assignment attributable to how clinicians summarize patient information into existing definitions of psychiatric diagnoses. Inadequacies of early diagnostic systems (e.g., the *Diagnostic and statistical manual of mental disorders* [*DSM-I* and *DSM-II*]) generally arose from the lack of explicit diagnostic criteria. The development of newer diagnostic schemes such as the Research Diagnostic Criteria (RDC; Spitzer, Endicott, & Robins, 1978), and subsequently the *DSM-III* (American Psychiatric Association, 1980), provided inclusion and exclusion criteria and specific criteria relating to symptoms, signs, duration and course, and severity of impairment.

In addressing errors that arise from inadequate nosology, clinicians and researchers are still faced with information variance, that is, errors originating from differences in what information is obtained and how that information is used by the interviewers. As reviewed above, Ward et al. (1962) found that nearly a third of diagnostic disagreements were related to the interviewers. Structured interviews were developed in order to address this source of error variance, and the history of structured interviews goes back to the 1950s (Spitzer, 1983). All structured interviews seek to minimize information variance by ensuring that clinicians systematically cover all relevant areas of psychopathology. Although specific methods vary across instruments, common techniques that characterize structured interviews are the specification of questions to be asked to assess domains of psychopathology and the provision of anchors and definitions in order to determine the ratings of symptoms (e.g., do the descriptions obtained within the interview achieve diagnostic threshold or not?). Despite some shared qualities it is also clear that available structured interviews differ markedly on a number of dimensions. The reliability of diagnoses based on refined diagnostic criteria paired with structured interviews was found to be greatly improved (e.g., Endicott & Spitzer, 1978; Spitzer, Endicott, & Robins, 1978).

4.05.1.1 Evaluating Structured Interviews

The selection of a structured interview will be driven by a number of other concerns. Some of the potential considerations are summarized in Table 1 and are derived from the reviews of Page (1991) and Zimmerman (1994). Questions that should be asked in selecting an instrument will include the diagnoses covered by the interview, the nosological criteria adhered to in generating these diagnoses (e.g., *DSM*, the *International classification of diseases* [*ICD*], or other criteria such at the RDC), and the population studied (e.g., adult or child). Additionally, the context in which the interview is conducted may also be relevant. That is, who will be administering the questionnaire and under what circumstances? Some interviews were developed to be used by lay interviews as in community epidemiological studies while other instruments require extensive clinical experience and are to be administered only by mental health professionals. Other concerns will relate to the guidelines and support available for an instrument. Some measures have extensive book-length user's manuals with available training videotapes and workshops; however, other measures have only sparse unpublished manuals with no training materials available. Finally, major concerns arise regarding reliability.

4.05.1.1.1 Reliability

The reliability of a diagnostic interview refers to the replicability of diagnostic distinctions obtained with the interview. Methods for evaluating agreement between two or more raters can take a variety of forms (Grove, Andreasen, McDonald-Scott, Keller, & Shapiro, 1981). Importantly, these differing methods may have an impact on indices of reliability. The most stringent evaluation involves raters conducting separate interviews on different occasions with diagnoses based only on interview data (i.e., no access to medical records or collateral informants such as medical staff or family members). Reliability assessment based on this method is referred to as "test–retest reliability," given the two occasions of interviewing. This methodology ensures a rigorous evaluation of the ability of the interview to limit information variance and to yield adequate information for the determination of diagnoses. However, in addition to interviewing style and methods of diagnosticians, two other factors contribute to rater disagreements in test–retest designs. First, the information provided by the patient may be different during the two interviews. Even with structured interviews this can continue to be a relevant source of variance. In a review of test–retest data using the Schedule for Affective Disorders and Schizophrenia, Lifetime Anxiety, Fyer et al. (1989) found that more than 60% of diagnostic disagreements were due to variation in the information provided by subjects. Second, there may be a true change in the clinical status of the individual who is interviewed. As the test–retest period increases, the potential contribution of changing clinical status will increase.

Other methods sometimes utilize a single interview that is either observed or videotaped and rated by independent (nonparticipating) raters, yielding inter-rater agreement. This method may yield inflated estimates of reliability as information variance is absent; that is, both raters are basing diagnostic decisions on the same subject responses. Also, interviewer behavior may disclose diagnostic decisions to the second rater. For example, during a structured interview an interviewer may determine that a module of the interview is not required based on subject responses and the interviewer's interpretation of rule-out criteria. The observing rater is aware of this diagnostic decision as the interviewer skips questions and moves to another module. Given the importance of methods used in assessing reliability, throughout this chapter we will attempt to indicate clearly the techniques by which reliability was assessed for each instrument.

In addition to considering study designs used in evaluating diagnostic reliability, it is also important to examine the statistics used to compute reliability. One method that has been used as an index of reliability is percent agreement. As outlined by Shrout, Spitzer, and Fleiss (1987), percent agreement is inflated by chance agreement and the base rates with which disorders are diagnosed in a sample. In their example, if two clinicians were randomly to assign *DSM* diagnoses to 6% of a community sample of 100 persons, chance agreement would produce an overall rate of agreement of about 88.8% (Shrout et al., 1987).

The index of agreement, kappa (K), was developed to address this statistical limitation (Cohen, 1960). Kappa reflects the proportion of agreement, corrected for chance; it varies from negative values reflecting agreement below chance, zero for chance agreement, and positive values reflecting agreement above chance to 1.0 for perfect agreement (Spitzer, Cohen Fleiss, & Endicott, 1967). The statistic weighted K was

Table 1 Relevant questions for selecting a diagnostic interview.

Content

Does the interview cover the relevant diagnostic system (e.g., RDC, *DSM-IV, ICD-10*)?
As an alternative to adhering to a single diagnostic system, does the interview provide polydiagnostic assessment (i.e., diagnoses for multiple diagnostic systems can be generated)?
Does the interview cover the relevant disorders?
Can irrelevant disorders be omitted?
Does the interview provide a sufficiently detailed assessment? That is, aside from diagnostic nosology is adequate information in other domains assessed (e.g., course of illness, family environment, social functioning)?
How are signs and symptoms rated (e.g., dichotomous ratings of presence vs. absence or continuous ratings of severity)?

Population

Is the interview applicable to the target population?
Relevant population considerations include adult vs. child, patient or nonpatient, general population, or family members of psychiatrically ill probands and whether the instrument will be used cross-culturally (is it available in languages for the cultures to be studied?).
Aside from general population considerations are there other exclusionary conditions to be aware of (e.g., age, education, cognitive functioning, or exclusionary clinical conditions)?

Time period

Does the interview cover the relevant time period (e.g., lifetime occurrence)?
Can the interview be used in longitudinal assessments to measure change?

Logistics of interview

How long does the interview take?
Does interview require or suggest use of informant (e.g., with child interviews)?

Administration/interviewer requirements

Who can administer the interview (e.g., lay interviewers, mental health professionals)?
How much training or experience is required to administer interview?
Does interview provide screening questionnaire to assist in expediting the interview (e.g., in personality disorder assessments)?
Are computer programs required and compatible with available equipment?

Guidelines and support

What guidelines for administration and scoring are available (e.g., user's manual)?
What training materials are available (videotapes, workshops)?
Is consultation available for training or clarification of questions regarding administration or scoring?

Reliability and validity

Is the interview sufficiently reliable?
Are reliability data available for the diagnoses and populations to be studied?
Are validity data available for the interview (e.g., concordance with other structured interviews, expert-obtained longitudinal data, and other noninterview measures)?

developed for distinguishing degrees of disagreement, providing partial credit when disagreement is not complete (Spitzer et al., 1967).

Standards for interpreting kappa suggest that values greater that 0.75 indicate good reliability, values between 0.50 and 0.75 indicate fair reliability, and values below 0.50 reflect poor reliability (Spitzer, Fleiss, & Endicott, 1978). Although the present review will adhere to the recommendations of Spitzer, Fleiss & Endicott (1978) that kappas below 0.50 indicate poor agreement or unacceptable reliability, it should be noted that other authors have proposed what appear to be more lenient criteria for evaluating kappa. For example, Landis and Koch (1977) suggest that kappas as low as 0.21–0.40 be considered as indicating "fair" agreement.

It is important to understand that reliability is not a quality inherent within an instrument that is transportable to different investigators or populations. All the measures described herein require interviewer training, and some instruments require an extensive amount of prior clinical experience and professional training.

Ultimately, the reliability of any structured interview will be dependent on the user of that interview. Although the present review will invite comparisons of reliability across studies it should be noted that reliability statistics such as kappa are influenced by a number of factors that constrain such comparisons. Differences in population heterogeneity, population base rates, and study methods will all influence reliability and should be considered in evaluating the literature.

4.05.1.1.2 Validity

In addition to reliability, the validity of a diagnostic assessment can also be evaluated. In the absence of an infallible or ultimate criterion of validity for psychiatric diagnosis, Spitzer (1983) proposed the LEAD standard: longitudinal, expert, and all data. Longitudinal refers to the use of symptoms or information that may emerge following an evaluation in order to determine a diagnosis. Additionally, expert clinicians making independent diagnoses based on all sources of information make a consensus diagnosis that will serve as a criterion measure. These expert clinicians should use all sources of data that have been collected over the longitudinal assessment including direct evaluation of the subject, interviewing of informants, and information from other professionals such as ward nurses and other personnel having contact with the subject. Typically, validity data such as that suggested by Spitzer are rarely available for structured interviews.

4.05.1.2 Overview

Within this chapter we provide an overview of the major structured interviews available for use with adult and child populations. The interviews included in this chapter are listed in Table 2. Due to space limitations we have focused on the review of broad diagnostic instruments and have not reviewed more narrow or specialized instruments that may address a single diagnosis or category of diagnoses. Each instrument will be reviewed with regard to its history and development and description of the instrument including its format and the diagnoses covered. Reliability data available will be presented and reviewed. Finally, a summary will be provided that intends to highlight the advantages and disadvantages inherent in each instrument. Interviews reviewed will address adult disorders, including personality disorders, and interviews for children and adolescents.

4.05.2 ADULT DISORDERS

4.05.2.1 Schedule for Affective Disorders and Schizophrenia

In order to address sources of diagnostic error arising from criterion variance, Spitzer, Endicott, and Robins (1978) developed the RDC. The RDC contains specific inclusion and exclusion criteria for 25 major diagnostic categories as well as subtypes within some categories. Disorders covered include schizophrenia spectrum disorders, mood disorders (depression and bipolar disorders), anxiety disorders (panic, obsessive-compulsive disorder, phobic disorder, and generalized anxiety disorder), alcohol and drug use disorders, some personality disorders (cyclothymic, labile, antisocial), and two broad categories of unspecified functional psychosis, and other psychiatric disorder. The major source of data for determining RDC diagnoses is the use of the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978).

As originally developed there were three versions of the SADS: the regular version (SADS), the lifetime version (SADS-L), and a change version (SADS-C). A lifetime anxiety version of the SADS (SADS-LA; Fyer et al, 1989; Mannuzza et al., 1989) has been developed to assess RDC, *DSM-III*, and *DSM-III-R* criteria for almost all anxiety disorder diagnoses, in addition to all the diagnoses covered in the original SADS. The SADS has two parts: Part I provides a detailed description of current condition and functioning during the one week preceding the interview, Part 2 assesses past psychiatric disturbance. The SADS-L is similar to Part 2 of the SADS but the SADS-L focuses on both past and current disturbance. It is appropriate for use in populations where there is likely no current episode or when detailed information regarding the current condition is not required. Endicott and Spitzer (1978) estimate that the SADS can be completed in one and one-half to two hours depending on the disturbance of the individual being interviewed.

The SADS provides probe questions for each symptom rating. However, in addition to using the interview guide the rater is instructed to use all sources of information and to use as many supplemental questions as is required to make ratings. Part 1 of the SADS rates severity of symptoms when they were at their most extreme. Many items are rated for severity during the week prior to the interview and for severity during their most extreme during the current episode. Ratings are made on a seven-point scale from zero (no information) to six (e.g., extreme). The SADS provides defined

levels of severity for each item. For example, in the screening items for manic criteria the item "less need for sleep than usual to feel rested" ratings are as follow: 1 = no change or more sleep needed; 2 = up to 1 hour less than usual; 3 = up to 2 hours less than usual; 4 = up to 3 hours less than usual; 5 = up to 4 hours less than usual; 6 = 4 or more hours less than usual.

In addition to the item ratings and the assignment of RDC diagnoses, the SADS can be used to provide eight summary scales: Depressive Mood and Ideation, Endogenous Features, Depressive-Associated Features, Suicidal Ideation and Behavior, Anxiety, Manic Syndrome, Delusions-Hallucinations, Formal Thought Disorder. These scales were determined by factor-analytic work using similar content scales, and an evaluation of clinical distinctions that are made in research of affective and schizophrenic disorders. The intent of the scales is to provide a meaningful summary of SADS information.

The SADS is intended for use by individuals with experience in clinical interviewing and diagnostic evaluation. Since clinical judgments are required in determining the need for supplemental questioning and in determining ratings, Endicott and Spitzer (1978) suggest that administration of the interview be limited to psychiatrists, clinical psychologists, or psychiatric social workers. However, these authors do note that interviewers with different backgrounds may be used but will require additional training. In one study using highly trained raters (Andreasen et al., 1981), reliability in rating videotaped SADS interviews was not affected by level of education (from medical degrees and doctorates in psychology to masters and other degrees) or years of prior clinical experience (from less than four years to more than 10 years).

Training videotapes and training seminars are available from the developers of the SADS at the New York State Psychiatric Institute, Columbia University. One example of training in the SADS is provided by Mannuzza et al. (1989) in the use of the SADS-LA. Training was conducted in three phases consisting of 50–60 hours over three to four months. In Phase 1 raters spent 20 hours attending lectures covering diagnosis, systems of classification, interviewing technique and the SADS-LA rater manual, reviewed RDC and *DSM-III* vignettes, and rated videotapes of interviews. In Phase 2 each rater administered the SADS-LA with one patient with an expert trainer and other raters observed. Interviews were subsequently reviewed and discussed. In the final phase, raters independently interviewed three or four patients who had already received the SADS-LA from an expert rater. This final phase allowed for test–retest reliability to be examined and provided an opportunity to discuss discrepancies in ratings during a consensus meeting.

4.05.2.2 Reliability

Initial reliability data for the SADS were reported by Spitzer, Endicott, and Robins

(1978) and Endicott and Spitzer (1978) for both joint interviews ($N = 150$) and independent test–retest interviews, separated by no more than one week ($N = 60$). For joint interviews, present and lifetime RDC diagnoses obtained kappas greater than 0.80 (median $K = 0.91$), with the exception of minor depressive disorder ($K = 0.68$). For test–retest interviews, reliability was somewhat attenuated but remained high with kappas greater than 0.55 for all disorders (median $K = 0.73$) with the exception of bipolar I (0.40). Endicott and Spitzer (1978) also reported reliability of the SADS items and eight summary scales using these same samples. For the 120 items of the current section of the SADS, reliability was high for both joint (90% of items interclass correlation coefficients [ICCs] equal to or greater than 0.60) and test–retest interviews (82% of items ICCs greater than or equal to 0.60). Summary scales also yielded high reliability for joint (ICC range = 0.82–0.99, median = 0.96) and test–retest interviews (ICC range = 0.49–0.91, median = 0.83). Spitzer et al. (1978) also examined the reliability of the SADS-L with first-degree relatives of patient probands ($N = 49$). All kappas were 0.62 or higher with the exception of other psychiatric disorder (0.46), median kappa = 0.86.

Two subsequent studies examined test–retest reliability (separate interviews conducted on the same day) of the SADS (Andreasen et al., 1981; Keller et al., 1981). In a study of 50 patients using the SADS-L, Andreasen et al. (1981) found ICCs equal to or greater than 0.62 for the major RDC diagnoses of bipolar I and II, major depressive disorder, alcoholism, and never mentally ill. The RDC subtypes of major depression also achieved ICCs equal to or greater than 0.60 with the exception of the subtype of incapacitating. Keller et al. (1981), using the SADS-L in a sample of 25 patients, obtained kappas equal to or greater than 0.60 for the RDC diagnoses of schizophrenia, schizoaffective-depressed, manic, major depressive disorder, and alcoholic. The major diagnoses of schizoaffective-manic and hypomanic had low reliability with kappas of 0.47 and 0.26, respectively. Keller et al. (1981) also found high reliability for background information items on social and educational background, and history of hospitalization (kappas greater than 0.73). Finally, individual items from manic, major depressive disorder, psychosis, alcohol and drug abuse, suicidal behavior, and social functional all achieved kappas above 0.56.

McDonald-Scott and Endicott (1984) evaluated the influence of rater familiarity on diagnostic agreement using the SADS. In this study modified SADS-C ratings were compared for two raters: one with extensive familiarity about subject's psychiatric history and course of illness and prior history and one who was blind to this history and had no prior contact with the subject. Quasi-joint interviews were conducted with the two raters. The nonblind rater was allowed to ask additional questions following the joint SADS interview, in the absence of the blind rater. Of four SADS-C summary scale scores all achieved ICCs of 0.79 or greater. At the item level, 92% of the 52 items had ICCs of 0.60 or greater. Rater differences in scoring suggested that the blind rater may have been somewhat more sensitive to items relating to dysphoria while the nonblind rater was more likely to identify some symptoms that may have been minimized or missed in the blind rater's interview (e.g., mania). However, these discrepancies were subtle and suggest that the SADS can achieve accurate assessment of current cross-sectional functioning whether or not raters have familiarity with the patient.

The inter-rater reliability of the SADS-derived *DSM-III* diagnoses in adolescents has been examined by Strober, Green, and Carlson (1981). Joint interviews were conducted with 95 inpatient adolescents and a family member. Raters independently reviewed all available collateral information prior to the SADS interview (e.g., medical and psychiatric records, school records, current nurses' observations). All diagnoses achieved kappas of 0.63 or greater with the exception of anxiety disorders of childhood (0.47) and undiagnosed illness (0.47). Although encouraging, these data should be viewed in the context of the use of joint interviews and the extensive use of collateral information to supplement the SADS.

Mannuzza et al. (1989) examined the reliability of the SADS-LA in a sample of 104 patients with anxiety disorders. Independent interviews were conducted with test–retest periods ranging from the same day to 60 days. Collapsing across RDC, *DSM-III*, and *DSM-III-R* anxiety disorder diagnoses, agreement for lifetime disorders achieved kappas of 0.60 or greater, with the exception of simple phobia. Examining lifetime anxiety diagnoses separately for each diagnostic system again suggested adequate reliability for most disorders (K range = 0.55–0.91), with the exception of RDC and *DSM-III-R* diagnoses of simple phobia and generalized anxiety disorder (Ks less than 0.49). Using this same sample, Fyer et al. (1989) assessed item reliability and factors contributing to disagreements. In general, symptoms were reliably rated with the exception of stimulus-bound panic (typical of simple phobia), near panic attacks, persistent generalized anxiety, six social and nine nonsocial irrational fears. Review of narratives and consensus meeting forms by Fyer et al. (1989) suggested that the largest source of disagreement was variation in information provided by subject (more than 60% of disagreements). Differences in rater interpretation of criteria resulted in 10–20% of the disagreements and rater error accounted for 10% of the disagreements.

The prior studies have examined test–retest reliability of lifetime diagnoses over brief periods. Two studies have examined the long-term test–retest reliability of SADS-L diagnoses. Bromet, Dunn, Connell, Dew, and Schulberg (1986) examined the 18-month test–retest reliability of the SADS-L in diagnosing lifetime major depression in a community sample of 391 women. Whenever possible, interviewers conducted assessments with the same subject at both interviews. Overall, reliability of lifetime diagnoses of RDC episodes of major depression was quite low. Of those women reporting an episode of major depression at either interview for the period preceding the first assessment, only 38% consistently reported these episodes at both interviews (62% reported a lifetime episode on one occasion but not another). For those women meeting lifetime criteria for a depressive episode at the first interview, fully 52% failed to meet criteria at the time of the second interview.

In a large-scale study of 2226 first degree relatives of probands participating in the National Institute of Mental Health (NIMH) Collaborative Program on the Psychobiology of Depression study, Rice, Rochberg, Endicott, Lavori, and Miller (1992) examined the stability of SADS-L-derived RDC diagnoses over a six-year period. The rater at the second interview was blind to the initial SADS-L. A large degree of variability in reliability was obtained for RDC diagnoses, with kappas ranging from 0.16 to 0.70. Diagnoses with kappas greater than 0.50 included major depression, mania, schizoaffective-mania, alcoholism drug use disorder, and schizophrenia. Diagnoses with low reliability as reflected by kappas below 0.50 were hypomania, schizoaffective-depressed, cyclothymia, panic disorder, generalized anxiety disorder, phobic disorder, antisocial personality, and obsessive-compulsive disorder. Rice et al. (1992) suggested that diagnostic reliability increases with symptom severity. In the studies of Bromet et al. (1986) and Rice et al. (1992), results indicated that there may be substantial error in the temporal stability of some SADS-L-derived lifetime diagnoses. This error may be particularly problematic in nonclinical community samples as studied in these investigations.

4.05.2.2.1 Summary

The development of the SADS represented significant progress in clinical assessment. The SADS has been used extensively in a number of research studies and a wealth of reliability data are available. The SADS provides a broad assessment of symptoms as well as severity ratings for many symptoms. However, the range of disorders covered is somewhat narrow (with an emphasis on schizophrenia, mood disorders, and anxiety disorders in the SADS-LA). Additionally, diagnostic criteria are based on the RDC, with the exception of anxiety disorders covered in the SADS-LA which provide *DSM-III-R* diagnoses.

4.05.2.3 Present State Examination

The Present State Examination (PSE) grew out of research projects in the UK requiring the standardization of clinical assessment. The PSE was not developed as a diagnostic instrument, as with the SCID and SADS. Rather, the PSE was intended to be descriptive and facilitate investigation of diagnostic rules and practices. At the time of the first publication of this instrument (Wing, Birley, Cooper, Graham, & Isaacs, 1967), the PSE was in its fifth edition. Currently, the ninth edition is widely used (Wing, Cooper, & Sartorius, 1974) and the tenth edition of the PSE is available (Wing et al., 1990). The PSE has been translated into over 40 languages and has been used in two large-scale international studies: the US–UK Diagnostic Project (Cooper et al., 1972) and the International Pilot Study of Schizophrenia (IPSS; World Health Organization, 1973).

The standardization of the PSE is achieved through the provision of a glossary of definitions for the phenomena covered by the interview. Additionally, specific series of questions with optional probes and cut-off points are also provided. Detailed instructions for rating the presence and severity of symptoms is also available. Despite this standardization, the developers have emphasized that it remains a clinical interview. The examiner determines the rating provided, evaluates the need for additional probe questions, and uses a process of cross-examination to address inadequate or inconsistent responses. As the name implies, the PSE was developed to ascertain present symptomatology and focuses on functioning in the month prior to the interview.

The eighth edition of the PSE was comprised of 500 items which were then reduced to 140 symptom scores. The ninth edition of the PSE reduced the number of items by having the 140 symptoms rated directly (the presence or absence of a symptom can be determined without asking as many questions, although additional probe questions are maintained in the ninth edition). Items receive one of three ratings. A zero indicates that a symptom is not present. If present, a symptom is rated as either one (moderate) or two (severe). Items are grouped into symptom scores based on item content and infrequency (Wing et al., 1974). The eighth edition takes approximately one hour to complete while the ninth edition takes approximately 45 minutes (Wing et al., 1974).

Symptoms can be further reduced to 38 syndrome scores by grouping together symptoms of similar content. For example, in the ninth edition the symptoms of worrying, tiredness, nervous tension, neglect through brooding, and delayed sleep are combined into the syndrome score of "Worrying, etc." These syndrome scores were intended to aid in the process of diagnosis by reducing the information to be considered, provide descriptive profiles, and provide a brief method of summarizing clinical information from other, non-interview, sources such as medical records by using a syndrome checklist.

Following the rating of items, a computer program (CATEGO) can be used to summarize PSE ratings further. For the ninth edition, the CATEGO program provides syndrome scores along with summary data for each syndrome (e.g., scores on constituent items). In the next stage, the program further summarizes the syndrome scores into six descriptive categories. The certainty of each descriptive category is also indicated (three levels of certainty are provided). Finally, a single CATEGO class (of 50) is assigned. Importantly, Wing (1983) has emphasized that the PSE and CATEGO program were not developed as diagnostic instruments *per se*. The CATEGO category or class assignments should not be considered diagnoses in the sense of DSM or ICD nosology. Rather, these summaries are provided for descriptive purposes. However, data from the US–UK Diagnostic Project and the IPSS have indicated reasonable convergence between CATEGO classes and clinical project diagnoses, especially when clinical history information is added to the PSE (reviewed in Wing et al., 1974).

Although short training courses lasting one week are available at various centers including the Institute of Psychiatry in London, Wing (1983) suggests that more extensive training is necessary. Wing (1983) recommends that at least 20 interviews be conducted under supervision in order to determine competency in administration of the PSE. Luria and Berry (1980) describe the stages of training used by these authors to achieve reliable PSE administration. In this study a general introduction and experience with unstructured symptom assessment was followed by reading and discussion of the PSE manual, the rating and discussion of 13 videotaped PSE interviews, and finally, participation in and observation of 12 live student-conducted PSE interviews followed by discussion.

4.05.2.3.1 Reliability

Early evaluations of the reliability of the PSE indicated promising agreement between raters. In the first reliability study conducted on early versions of the PSE (up to PSE-5), rater agreement was evaluated with both independent interviews and observation of interviews, or listening to audiotapes (Wing et al., 1967). Assignment to main categories suggested reasonable agreement, using percent agreement, of 83.7%. Examining five nonpsychotic symptoms, agreement also seemed satisfactory (range across studies $r = 0.53–0.97$). Reliability for nine psychotic symptoms, calculated for single interviews (tape recorded or observed) was also adequate (range of $r = 0.62–0.97$). Kendell, Everitt, Cooper, Sartorius, and David (1968) found a mean kappa for all items to be 0.77.

Luria conducted two reliability studies using the PSE-8 (Luria & McHugh, 1974; Luria & Berry, 1979). Luria and McHugh (1974) examined agreement using six videotaped PSE interviews. The authors examined agreement for 19 profiles of their own design. Patients were ranked on each category based on ratings of examiners. Reliability for these categories was generally adequate with Kendall's W coefficients greater than 0.73 except for behavioral items such as psychomotor retardation (0.66); excitement, agitation (0.47), catatonic, bizarre behavior (0.44); blunted, inappropriate, incongruous affect (0.60). In a subsequent study, Luria and Berry (1979) examined agreement on 20 symptoms deemed of diagnostic importance, 19 psychopathology profiles, and eight syndromes. Thirteen interviews were rated for reliability on the basis of videotapes; 12 were rated based on joint observational interviews. Reliability for videotape and live symptom ratings were adequate with median ICCs of 0.84 and 0.86, respectively (however, agitation or retardation and bizarre behaviors were judged to have poor reliability). Of the 19 profile ratings, the 13 had adequate reliability for videotaped (0.97) and live interviews (0.95). The six behavioral profiles were somewhat lower at 0.72 and 0.66, respectively. Syndrome agreement was high with generalized kappas above 0.91.

Three studies have examined inter-rater agreement for abbreviated versions of the PSE-8 and PSE-9 when used by nonpsychiatric raters (Cooper, Copeland, Brown, Harris, & Gourlay, 1977; Wing, Nixon, Mann, & Leff, 1977; Rodgers & Mann, 1986). Cooper et al. (1977) examined the agreement between ratings of a psychiatrist or psychologist and those obtained by a sociologist or sociology graduate student. Agreement was evaluated for both joint interviews and test–retest over one week. For joint interviews, with the exception of situational anxiety ($r = 0.34$), inter-rater agreement for the remaining 13 section scores was good, with correlations ranging from 0.65 to 0.96 (mean $r = 0.77$). Test–rest reliability was lower with five section scores having correlations below 0.40 and the mean for the 14 sections decreasing to 0.49. The correlation between total scores was 0.88 for inter-rater agreement and 0.71 for test–retest. Finally, presence vs. absence decisions for the 150 rated items indicated good reliability with a mean inter-rater kappa of 0.74, and a mean test–retest kappa of 0.54.

Wing et al. (1977) conducted two studies of a brief version of the PSE-9. In the first, 95 patients were interviewed independently (5–84 days between interviews) by a nonmedical interviewer and a psychiatrist. Agreement was examined for 13 syndromes and was unacceptably low with a mean kappa of 0.34 (range 0–0.49). The authors examined agreement on five symptoms relating to anxiety and depression. Poor agreement was found for these symptoms with kappas below 0.32. In the second study, 28 interviews were conducted by a nonmedical interviewer. Audiotapes of these interviews were rated by a psychiatrist. The mean kappa for syndrome scores was 0.52 (range = 0.25–0.85). Ratings of the five symptoms yielded kappas above 0.62 with the exception of free-floating anxiety ($K = 0.34$).

In a large population study, Rodgers and Mann (1986) assessed inter-rater agreement between nurses and a psychiatrist's rating of audiotapes. Audiotapes of 526 abbreviated PSE-9 interviews were evaluated. A statistic of index of association was used, although the authors report that this measure was highly correlated with kappa. Of 44 symptoms rated, six were considered too infrequent to evaluate. Of the remaining 38 symptoms the median index of association was 0.73 (range 0–0.96); seven items (18%) were unacceptably low in level of agreement (index of association less than 0.45): Expansive Mood, Ideomotor Pressure, Obsessional Checking/Repeating, Obsessional Ideas/Rumination, Hypochondriasis, Suicidal Plans or Acts, and Ideas of Reference. Thirteen syndrome scores derived from symptom ratings ranged from 0.29–0.94 (median = 0.76). Two syndrome scores were unacceptably low in agreement, Ideas of Reference (0.44) and Hypochondriasis (0.29).

In a recent study Okasha, Sadek, Al-Haddad and Abdel-Mawgoud (1993) examined rater agreement for assigning diagnosis based on *ICD-9*, *ICD-10*, and *DSM-III-R* criteria. The Arabic version of the PSE-9 was modified to collect extra data needed to make *ICD* and *DSM-III-R* diagnoses. One hundred adult inpatients and outpatients were interviewed by a single rater. An abstract form with PSE scores and other demographic and clinical information was then rated and diagnoses assigned. Overall kappa for nine broad diagnostic categories was acceptable (*ICD-9*, $K = 0.79$; *ICD-10*, $K = 0.82$; *DSM-III-R*, $K = 0.64$). Overall kappa values for more specific 18 diagnoses diminished somewhat but remained adequate (*ICD-9*, 0.62; *ICD-10*, 0.80, *DSM-III-R*, 0.63). Although this study indicates that PSE-9-derived information can be used to assign *ICD* and *DSM* diagnoses reliably it does not address the reliability of PSE-9 interviews themselves as diagnostic ratings were made from a single PSE abstract.

4.05.2.3.2 Supplements to the PSE

Two supplements to the PSE have been developed to address limitations in this instrument. These supplements address the assessment of lifetime psychopathology (McGuffin, Katz, & Aldrich, 1986) and change ratings (Tress, Bellenis, Brownlow, Livingston, & Leff, 1987). Because of the PSE's focus on the last month, its use in epidemiological studies is somewhat limited as these population-based investigations generally require the assessment of lifetime psychopathology. This concern led McGuffin et al. (1986) to modify the PSE. A Past History Schedule was developed to determine the dates of onset of worst episode of psychopathology, first psychiatric contact, and severest disturbance and recovery. Based on information obtained with the Past History Schedule, the PSE is then administered in three time formats: focusing on the last month, the most serious past episode, and modifying each PSE obligatory question with "have you ever experienced this?" Reliability assessment of this modified PSE using audiotaped interviews (McGuffin et al., 1986) has suggested adequate inter-rater agreement for the PSE CATEGO classes for past month (kappa range = 0.48–0.74), first episode (kappa range = 0.87–1), and ever (kappa range = 0.88–0.92). Rater agreement for dating past episodes was also found to be satisfactory (rank-order correlation coefficients, median = 0.83, range 0.54–0.99).

Tress et al. (1987) modified the PSE for purposes of obtaining change ratings. The authors suggest that the advantage of the PSE over other instruments available for ratings of clinical change are that the PSE gives data for clinical classification, provides clear definitions of items, and uses a structured interview format. The PSE Change Rating is administered following a standard PSE assessment. Items not rated positively on the initial assessment are discarded (as well as items that were not rated). Subsequent ratings are only made on these remaining items. These items are subsequently rated on an eight-point scale from zero (Completely Remitted) to seven (Markedly Worsened). Inter-rater agreement based on observed interviews was high for grouped symptom ratings (ICC range = 0.75–0.99) and selected individual symptoms (ICC range = 0.70–1).

4.05.2.3.3 Summary

As the first semistructured clinical interview the PSE has an extensive history with application in a number of studies. Additionally, the PSE has been translated into over 40 languages and has been employed in cross-cultural studies. A potential advantage of the PSE is that it is not constrained by a particular diagnostic system; however, the PSE-10 was designed to yield *ICD-10* and *DSM-III-R* diagnoses (Wing et al., 1990). The reliability data for the PSE are constrained in that assessments have included a variety of versions and modifications of the PSE using raters with a variety of training with different populations. Caution should be exercised in applying these data to an investigator's own intended use. Furthermore, reliability data for the PSE-10, which has undergone substantial revision, are not yet available, although a multisite investigation has been conducted (Wing et al., 1990). Additionally, examination of diagnostic reliability achieved with the PSE, while encouraging, has been limited to a few diagnoses and are not available for *DSM-IV*.

4.05.2.4 Structured Clinical Interview for *DSM-IV*/Axis I Disorders

The Structured Clinical Interview for *DSM-IV* (SCID-I) is a semistructured interview designed to assist in determining *DSM-IV* Axis I diagnoses (First, Gibbon, Spitzer, & Williams, 1996). Construction of the interview began in 1983 following the introduction of the *DSM-III*, which introduced operationalized, specific behavioral criteria. At this time existing clinical structured diagnostic interviews became limited in that they did not conform to the *DSM-III* criteria (e.g., the SADS and PSE). Although the Diagnostic Interview Schedule (DIS) was developed to yield *DSM-III* diagnoses, the DIS was designed to be used by lay interviewers in epidemiological studies. It was argued by Spitzer (1983) that the most valid diagnostic assessment required the skills of a clinician so that the interviewer could rephrase questions, ask further questions for clarification, challenge inconsistencies, and use clinical judgment in ultimately assigning a diagnosis. Thus, the SCID was initially developed as a structured, yet flexible, clinical interview for *DSM-III*, and subsequently *DSM-III-R*, diagnoses (Spitzer, Williams, Gibbon, & First, 1992).

The SCID-I has been revised several times due to criteria changes and field trials. The interview was primarily developed for use with adults, but may be used with adolescents. It is contraindicated for those with less than an eighth grade education, severe cognitive impairments, and experiencing severe psychotic symptoms (First et al., 1996). The SCID-I is available in Spanish, German, Portuguese, Dutch, and Hebrew, as well as English.

Separate versions of the SCID-I have been developed for research and clinical applications. The clinical version, the SCID-I-CV, is briefer than the research version and focuses primarily on key diagnostic information (excluding the supplementary coverage provided in the research version) and on the most commonly occurring diagnoses (First et al., 1996). Within the research version, three variations of the interview provide differing comprehensive coverage of the disorders, subtypes, severity, course specifiers, and history. The research versions have been used historically for inclusion, exclusion, and data collection of study participants (in over 100 studies), and are distributed in loose page format to allow the investigator to customize the SCID-I to meet the needs of their research. The SCID-P (patient edition) was designed to address psychiatric patients and provides thorough coverage of psychotic disorders and past psychiatric history. The SCID-NP (nonpatient edition) was developed to focus on nonpsychiatric patients, and subsequently screens for psychotic disorders and provides less comprehensive coverage of psychiatric history. The SCID-P with Psychotic Screen was developed for patients where a psychotic disorder is not expected (and therefore only screens for psychotic disorders), but has thorough coverage of psychiatric history.

The SCID-I can usually be administered in 60 to 90 minutes, contingent on the quantity of symptoms and disorders, and the ability of the interviewee to describe problems succinctly. It begins with an introductory overview followed by nine diagnostic modules. The overview provides open and closed questions that not only gather background information, but allows the interviewer to establish rapport with the interviewee before more detailed (and potentially uncomfortable) diagnostic questions are asked. The overview gathers information on demographics, work history, medical and psychiatric history, current stressors, substance use, and the interviewee's account of current and past problems (First et al., 1996).

There are nine diagnostic modules focusing on both current (usually defined as the past month) and lifetime assessment of diagnostic criteria: Mood Episodes, Psychotic Symptoms, Psychotic Disorders, Mood Disorders, Substance Use Disorders, Anxiety Disorders, Somataform Disorders, Eating Disorders, and Adjustment Disorders. An optional module covers Acute Stress Disorder, Minor Depressive Disorder, Mixed Anxiety Depressive Disorder, and symptomatic details of past Major Depressive/Manic episodes. Each page of the modules contains questions, reprinted *DSM-IV* criteria, ratings, and instructions for continuation. Initial questions are closed-ended and followed up with open-ended elaboration questions. If further clarification is needed, the interviewer is encouraged to ask supplementary (their own) questions, give examples, present hypothetical situations, and challenge inconsistencies. In essence, the interviewer is testing diagnostic hypotheses. The ratings are based not on the question response, but on fulfillment of *DSM-IV* criteria which are provided alongside the questions. The interviewer is encouraged to use alternate sources of information to assist in rating the criteria, such as observed behavior, medical records, and informants. Each criteria is rated as one of the following: ? = inadequate information, 1 = symptom clearly absent or criteria not met, 2 = subthreshold condition that almost meets criteria, and, 3 = threshold for criteria met.

Unlike other diagnostic interviews such as the SADS, PSE, or DIS, where diagnostic algorithms are applied following the interview, the SCID incorporates diagnostic criteria and decision making within the interview. The use of a "decision-tree approach" allows the interviewer to test hypotheses and concentrate on more problematic areas (Spitzer, Williams, Gibbons & First, 1992). In addition, this approach makes the interview more time efficient, allowing the interviewer to "pass over" areas of no concern. Following the interview, the interviewer is provided with concise summary scoring sheets to indicate the lifetime absence or threshold, and current presence of each disorder.

As a prerequisite for the SCID-I, the interviewer must possess adequate clinical experience and knowledge of psychopathology and diagnostic issues. The test developers recommend the following training: reading the administration sections of the *User's guide for the SCID-I*, reading the entire test booklet, reading the questions orally, practicing the SCID-I on a colleague/friend, watching a six-hour didactic training videotape titled *SCID-I 201*, role playing sample cases in the *User's guide for the SCID-I*, administering on an actual subject, conducting joint interviews (with independent ratings) followed by discussion sections, and examining inter-rater and test–retest reliability among interviewers (First et al., 1996). The following training materials and services are available: *User's guide for the SCID-I*, *SCID-I 201* video tape, videotape samples of interviews, on-site training, off-site monitoring, and SCID-I certification (under development). Following training, interviewers would benefit from ongoing supervision and feedback from an experienced SCID-I interviewer.

4.05.2.4.1 Reliability

Inter-rater agreement for the *DSM-III-R* version of the SCID-I was examined for 592 patients in five inpatient sites (one in Germany) and two nonpatient sites (Williams et al., 1992). At each site, two clinicians independently interviewed and diagnosed patients at least 24 hours but less than two weeks apart. In order to limit access to other information (e.g., chart review), interviewers were provided with only a brief summary of the hospital admission evaluation (circumstances of admission, number of prior hospitalizations, presenting problems). Diagnostic terms were excluded from the summary. For patients, overall weighted kappa was 0.61 for 18 current and 0.68 for 15 lifetime *DSM-III-R* diagnoses common to these sites. Disorders with poor agreement (i.e., *K*s below 0.50) were current diagnoses of dysthymia, agoraphobia without panic disorder, and social phobia, and the lifetime diagnosis of agoraphobia without panic disorder. Agreement for specific substance dependence diagnoses at a drug and alcohol treatment facility was high with all diagnoses having kappas above 0.61 except cannabis dependence and polydrug dependence (both kappas below 0.35). For nonpatients, overall weighted kappa was 0.37 for five current diagnoses and 0.51 for seven lifetime diagnoses common to these sites. The only diagnoses in nonpatients with a kappa of 0.50 or greater were current panic disorder, and lifetime diagnoses of alcohol dependence/abuse, other drug dependence/abuse, and panic disorder. Due to low occurrences, data were inconclusive for infrequent diagnoses.

Although generally satisfactory, these findings do indicate low agreement for some diagnoses. Williams et al. (1992) suggest several possible causes for low rater agreement in this study including the restriction of noninterview information, the focus on a broad range of diagnoses, and the flexible nature of the SCID in using clinical judgment. With regard to this last point, a review of a sample of audiotapes indicated that diagnostic disagreements were largely due to one interviewer's acceptance of a yes response without requesting elaboration while the other interviewer asked follow-up questions that ultimately determined that an initial yes response did not meet diagnostic criterion. As concluded by Williams et al. (1992) maximizing reliability on the SCID requires extensive training in the diagnostic criteria and an emphasis on not taking shortcuts but requiring that descriptions of behavior are elicited to justify each criterion.

Several other studies offer data on the reliability of the SCID-I, but the findings are confounded by small number of participants, changing *DSM* criteria and SCID-I revisions during the study, low base rates of disorders, and limited range of disorders (Segal, Hersen, & Van Hasselt, 1994). However, higher inter-rater agreement was observed in these studies ($K = 0.70–1$) compared to that obtained by Williams et al. (1992). The differences may have been due to the use of joint interviews (which controls for subject report variance) rather than independent interviews, access to noninterview information such as medical records and reports from other clinical staff, and the focus on a narrower range of diagnoses assessed.

4.05.2.4.2 Summary

The SCID is a well-established structured interview for determining *DSM-III-R* and *DSM-IV* diagnoses. Users may find the inclusion of diagnostic algorithms within the SCID and the use of skip-outs to result in a time-efficient interview. Reliability data from multiple sites indicate that the SCID can provide reliable *DSM-IV* diagnoses. Additionally, the SCID has some of the most extensive training materials and support available for any structured interview. The interview, user's guide, and all training materials have been completely updated for *DSM-IV*.

There are, however, a few disadvantages of the SCID-I. The interview does not cover a number of disorders, including infant, childhood, adolescence, cognitive, factitious, sexual, sleep, and impulse control disorders. Also, for those individuals interested in other diagnostic nosologies or needing to obtain broader clinical assessments, the restriction of the SCID to *DSM-IV* might be limiting. As with other structured interviews there is as yet no information currently available on the reliability of the SCID-I for the *DSM-IV* criteria. However, minor changes in the diagnostic criteria should not adversely affect reliability obtained with the *DSM-III-R* version.

4.05.2.5 Comprehensive Assessment of Symptoms and History

The Comprehensive Assessment of Symptoms and History (CASH; Andreasen, 1987) was developed without adherence to existing diagnostic systems (such as the *DSM* or *ICD*). The CASH adopted this approach based on observations that diagnostic criteria change over time and that methods of collecting information that conform to these criteria may be quickly outdated (Andreasen, Flaum, & Arndt, 1992). The CASH was designed for the study of psychosis and affective syndromes and is intended to provide a standardized assessment of psychopathology that will, ideally, yield diagnoses based on multiple criteria (both existing and future).

The CASH consists of nearly 1000 items divided into three sections: present state, past history, and lifetime history. The present state section consists of sociodemographic information intended to establish rapport and, subsequently, items pertaining to present illness. This section includes symptoms relating to the psychotic syndrome, manic syndrome, major depressive syndrome, treatment, cognitive assessment (laterality and a modified Mini-Mental Status Examination), a Global Assessment scale, and a summary of diagnoses for current episode.

Past history includes history of onset and hospitalization, past symptoms of psychosis, characterization of course, and past symptoms of affective disorder. To provide a detailed evaluation of phenomenology over time, for each symptom or sign, interviewers determine whether it was present during the first two years of illness, and whether it has been present for much of the time since onset. Finally, the lifetime history section includes history of somatic therapy, alcohol and drug use, premorbid adjustment, personality (schizotypal and affective characteristics), functioning in the past five years, Global Assessment scale and diagnoses for lifetime. Most items are given detailed definitions with suggested interview probes. Items are typically rated on a six-point Likert-type scale.

A number of measures are embedded within the CASH. Scales within the CASH include the Scale for Assessment of Negative Symptoms (Andreasen, 1983), Scale for Assessment of Positive Symptoms (Andreasen, 1984), most items for the Hamilton depression scale (Hamilton, 1960), and the Brief Psychiatric Rating Scale (Overall & Gorham, 1962), the Mini-Mental Status Exam (Folstein, Folstein, & McHugh, 1975), and the Global Assessment Scale (Endicott, Spitzer, Fleiss, & Cohen, 1976). These measures make the CASH useful for repeat assessments.

The CASH was intended for use by individuals with experience and training in working with psychiatric patients (e.g., psychologists, psychiatrists, nurses, or social workers). A training program has been developed for its use, which includes training videotapes conducted with patients presenting a range of psychopathology. Narratives and calibrated ratings for the CASH items are available from the authors

4.05.2.5.1 Reliability

A small reliability study conducted with 30 patients has been reported (Andreasen et al., 1992). Two forms of rater agreement were evaluated. First, patients were interviewed by a primary rater with a second rater observing and asking clarifying questions when necessary. Second, test–retest reliability was evaluated with a third rater interviewing the patient within 24 hours of the initial interview. All raters had access to medical records. Agreement between the two initial raters was generally good for the spectrum diagnoses (Schizophrenia Spectrum, $K = 0.86$; Affective Spectrum, $K = 1$). For specific *DSM-III-R* diagnoses (focusing on diagnoses with more than one case), the results were positive for schizophrenia ($K = 0.61$), bipolar affective disorder ($K = 1$), and major depression ($K = 0.65$). However, reliability for schizoaffective disorder was somewhat low ($K = 0.45$). Test–rest reliability was similarly positive with kappas above 0.74 for spectrum diagnoses and above 0.64 for specific *DSM-III-R* diagnoses with the exception of schizoaffective disorder ($K = 0.52$).

Because of the intent of the CASH to provide a reliable assessment of symptoms and functioning independent of diagnostic classification, it is important to examine the reliability of the individual items. Given the number of items, Andreasen et al. (1992) provide summaries of the intraclass correlation coefficients for the inter-rater and test–retest administrations. For inter-rater agreement, ICCs were generally high with three-quarters of the items having ICCs greater than or equal to 0.65. For the test–retest design, reliability was somewhat lower with approximately one-half of the items demonstrating ICC greater than or equal to 0.65.

Reliability data have been published for some more critical items or content areas (Andreasen et al., 1992). For history of illness, ICC values for both inter-rater and test–retest designs were quite adequate with values generally above 0.60 (median ICCs above 0.70). Reliability for items relating to manic and depressive syndromes was acceptable (median ICCs = 0.68 and 0.58, respectively). For positive and negative symptoms inter-rater and test–retest reliability was generally acceptable for "current" and "much of time since onset" time frames (global symptom scores ICCs greater than 0.65). However, test–retest reliability for negative symptoms rated for the "first two years of illness" and "worst ever" were unacceptably low (ICCs = 0 and 0.48, respectively). Test–retest data on premorbid and prodromal symptoms were very low (median ICCs = 0.37 and 0.25, respectively), while residual symptom ratings were somewhat better (median ICC = 0.60).

4.05.2.5.2 Summary

The CASH presents several advantages including its lack of adherence to any diagnostic system. This may afford the opportunity to collect a rich body of information on individuals. The comprehensiveness of the items is intended to allow for diagnoses for *DSM* and *ICD* to be generated while not narrowing the collection of information to these systems. Available reliability data are encouraging, with some exceptions as noted above. The availability of training materials including videotapes and consensus ratings is also attractive. The CASH also has companion instruments that are useful in the context of longitudinal assessments, providing baseline and follow-up assessment of psychosocial functioning and symptomatology.

The CASH is limited in several respects. First, because it seeks a full assessment of symptoms and history without regard to diagnostic criteria the entire CASH must be administered (however, some syndromes can be skipped if the interviewer already knows that a syndrome is not applicable). With nearly 1000 items this ensures lengthy assessment. Second, the CASH is limited to schizophrenia and affective syndromes and alcohol and drug use. Thus, it may not provide the breadth of symptom and diagnostic evaluation that some settings may require. Finally, although intended to be capable of assigning diagnoses based on extant nosological systems, the CASH may not always be capable of achieving this goal. Diagnostic criteria may require symptom information that does not conform to the information obtained with the CASH. Interested users should carefully evaluate the content of the CASH to ensure that relevant diagnoses can be made.

4.05.2.6 Diagnostic Interview for Genetic Studies

The Diagnostic Interview for Genetic Studies (DIGS; Nurnberger et al., 1994) was developed by participants in the NIMH Genetics Initiative. The need for the DIGS arose from perceptions that inconsistent findings in the genetics of psychiatric illnesses might be, in part, the result of differences in phenotypic assessment. Problems in assessment are highlighted in genetics research where family members are more likely to evince spectrum disorders and subclinical symptomatology.

The DIGS adopts a polydiagnostic approach that collects clinical information in sufficient detail to allow a variety of diagnostic definitions to be applied including *DSM-III-R* (a new version for *DSM-IV* is now available), modified RDC, RDC, Feighner criteria, *ICD-10*, and the European Operational Criteria (OPCRIT) Checklist (McGuffin & Farmer, 1990). As with the CASH, the advantage of this feature includes the collection of a broad data set for diagnostic entities whose definitions are sometimes ambiguous and evolving. However, the DIGS (unlike the CASH) explicitly collects information that conforms to several diagnostic systems including *DSM-IV*. Items from other interviews have been incorporated into the DIGS including the SADS, CASH, and DIS.

Like the SADS the DIGS provides standard probe questions and criterion-based definitions. Additionally, the DIGS requires clinical judgment for item ratings and in determining the need for further probe questions. Sections of the DIGS begin with one or two screening questions that, if denied, allow the interviewer to skip out of the remainder of the section. Questions are integrated so as to cover the various diagnostic criteria covered while maintaining an efficient flow of questioning. The interview can take 30 minutes to four hours depending on the complexity of the symptomatology (median time for symptomatic individuals is two and one-half hours).

The DIGS begins with a modified Mini-Mental Status examination in order to determine if the interview should be terminated as a result of cognitive impairment. The Introduction continues with demographics and extensive medical history screening questions. Somatization follows to enhance flow from medical history. An overview section assesses psychiatric history and course of illness and this information is summarized graphically in a time line to provide chronology of symptoms and episodes of illness. Mood disorders include major depression, mania/hypomania, and cyclothymic personality disorder. The DIGS also provides a detailed assessment of substance use history. Psychotic symptoms are assessed in great detail and psychotic syndromes are distinguished. Additionally, schizotypy is also assessed. A unique feature of the DIGS is an assessment for comorbid substance use. The aim of this section is to determine the temporal relationship between affective disorder, psychosis, and substance use. Suicidal behaviors, major anxiety disorders (except generalized anxiety disorder), eating disorders, and sociopathy are also evaluated. Finally, at the conclusion of the DIGS, the interviewer completes a Global Assessment scale (Endicott et al., 1976), the Scale for the Assessment of Negative Symptoms (Andreasen, 1983), and the Scale for the Assessment of Postive Symptoms (Andreasen, 1984).

Appropriate personnel to administer the DIGS are mental health professionals with clinical experience and familiarity with multiple diagnostic systems. In the study of Nurnberger et al. (1994), all but one interviewer had prior experience administering semistructured clinical interviews. Training as outlined in the reliability studies (Nurnberg et al., 1994) consisted of demonstration interviews by senior clinicians, the administration of a DIGS under supervision, and supplemental training involving three videotaped patient interviews.

4.05.2.6.1 Reliability

Test–retest reliability for the DIGS has been evaluated for major depression, bipolar disorder, schizophrenia, schizoaffective disorder and an "other" category (Faraone et al., 1996; Nurnberger et al., 1994). Test–retest reliability was evaluated within participating research sites as well as across sites. For the intrasite study, participants were independently interviewed with the DIGS over a period of no more than three weeks. For the intersite study, interviewers traveled to other research centers so that interviewers from different sites could assess the same subjects. These pairs of interviews were conducted within a 10-day period. With the exception of *DSM-III-R* schizoaffective disorder (K less than 0.50), *DSM-III-R* and RDC target diagnoses showed excellent reliability with kappas above 0.72 across the two studies.

4.05.2.6.2 Summary

The DIGS appears to be an excellent instrument for the study of the genetics of schizophrenia and affective disorders and other comorbid conditions. It provides an exhaustive assessment of symptomatology that allows for the comparison of findings across a number of diagnostic systems. Furthermore, it targets spectrum disorders and other comorbid conditions that may be relevant in family studies of schizophrenia and affective disorders. Although reliability has been shown to be high across different sites, these data are limited to schizophrenia and the affective disorders (but are not available for bipolar II and schizotypal personality); data are not available for other disorders such as the anxiety and eating disorders. As emphasized by the developers, the DIGS is not designed for routine clinical use. It is designed to be used by highly trained clinical interviewers for use in research settings.

4.05.2.7 Diagnostic Interview Schedule

The DIS (Robins, Helzer, Croughan, & Ratcliff, 1981) is a highly structured interview developed for use in large-scale epidemiological studies by the NIMH (the Epidemiological Catchment Area, ECA, projects). Because of the logistical constraints in general population studies, the use of traditional structured interviews administered by clinicians is prohibitive. The DIS was developed for use by lay interviewers with relatively brief training (one to two weeks). Thus, unlike structured interviews such as the SADS or SCID, the DIS minimizes the amount of discretion that an interviewer exercises in either the wording of questions or in determining the use of probe questions. Additionally, diagnoses are not made by the interviewer; rather, the data are scored, and diagnoses assigned, by a computer program.

The DIS was designed to provide information that would allow diagnoses to be made according to three diagnostic systems: *DSM-III* (APA, 1980), the Feighner criteria (Feighner et al. 1972), and the RDC. The interview covers each item or criterion in the form of one or more close-ended questions. Questions assess the presence of symptoms, whether they meet criteria for frequency and clustering in time, and whether they meet the age-at-onset criterion. The use of a Probe Flow Chart provides probes needed to determine severity and address alternative explanations. Rules concerning when and what probe questions to use are explicit in the interview. Nearly all questions can be read by lay interviewers as written. The DIS can take between 45 and 75 minutes to complete.

4.05.2.7.1 Reliability

vRobins et al. (1981) addressed the question of whether lay interviewers could obtain psychiatric diagnoses comparable to those obtained by a psychiatrist. In a test–retest design, subjects (mostly current or former psychiatric patients) were separately interviewed by a lay interviewer and a psychiatrist, both using the DIS. With the exception of *DSM-III* panic disorder ($K = 0.40$), kappas for all lifetime diagnoses across each diagnostic system were 0.50 or greater. Mean kappas for each diagnostic system were quite adequate: *DSM-III*, $K = 0.69$; Feighner, $K = 0.70$; RDC, $K = 0.62$. Further analysis of these data (Robins, Helzer, Ratcliff, & Seyfried, 1982) suggested that current disorders and severe disorders are more reliably diagnosed with the DIS than disorders in remission or borderline conditions.

Although the findings of Robins et al. (1981 1982) suggested acceptable concordance between lay interviewers and psychiatrists using the DIS, these data do not address whether the DIS would yield similar diagnoses as obtained by psychiatrists with broader clinical assessment than that allowed by the DIS alone. Additionally this first study was conducted with a largely psychiatric sample and may not be generalizable to the nonclinical populations the DIS was designed for. Anthony et al. (1985), using data from the ECA obtained in Eastern Baltimore, compared DIS-obtained diagnoses with psychiatrist-conducted clinical reappraisal examinations ($N = 810$). These clinical reappraisals were based on an augmented PSE consisting of 450 signs and symptoms and included all items of the PSE-9. Additionally, psychiatrists reviewed all available records. The two assessments were independent and the majority were completed within four weeks of each other. Diagnostic comparisons were for conditions present at the time of the interview or within one month prior to the interview. Results indicated substantial differences between DIS and psychiatrists' diagnoses. Except for schizophrenia and manic episode, one month prevalence rates for *DSM-III* diagnostic categories were significantly different for the two methods. Additionally, there was very low concordance between DIS-based diagnoses and those obtained by psychiatrists with kappas for selected diagnoses all below 0.36.

In a second major study based on ECA data collected in St. Louis, Helzer et al. (1985) compared lay-interview diagnoses with those obtained by a psychiatrist ($N = 370$). The psychiatrist re-examined subjects with the

DIS and were also allowed to ask whatever supplemental questions they deemed necessary to resolve diagnostic uncertainties following the DIS. The majority of psychiatrist interviews were conducted within three months of the lay interview. Diagnostic comparisons were made for lifetime diagnoses. Helzer et al.'s summary of the data was somewhat optimistic, indicating that corrected concordance was 0.60 or better for eight of the 11 lifetime diagnoses. However, when kappa statistics are examined, the results are less promising. Only one of eleven diagnoses obtained a kappa greater than or equal to 0.60, and eight diagnoses had kappas below 0.50. As summarized by Shrout et al. (1987) "for most diagnoses studied, the agreement in community samples between the DIS and clinical diagnoses is poor" (p. 177).

A number of other studies have been conducted comparing lay interviewer-administered DIS diagnoses with clinical diagnoses (e.g., Erdman et al., 1987; Escobar, Randolph, Asamen, & Karno, 1986; Ford, Hillard, Giesler, Lassen, & Thomas, 1989; Spengler & Wittchen, 1988; Wittchen, Semler, & von Zerssen, 1985; also see recent review by Wittchen, 1994). These studies are difficult to summarize and their interpretability is sometimes limited due to the use of a variety of assessment methodologies, diagnostic systems, and populations. Although some diagnoses achieve acceptable concordance levels between the DIS and clinical diagnoses, in total the results of these studies suggest limitations of the DIS consistent with the observations of Shrout et al. (1987). Wittchen (1994) has summarized particular problems apparent in the panic, somatoform, and psychotic sections of the DIS.

4.05.2.7.2 Summary

The DIS marked a significant development in the epidemiological study of psychopathology. The ECA findings based on the DIS have yielded important information about the epidemiology of a variety of disorders. However, studies examining the concordance between the DIS and clinical interviews conducted by psychiatrists suggest that there may be appreciable diagnostic inaccuracy in DIS-based diagnoses. Although the use of the DIS in epidemiological studies may continue to be warranted given the logistical constraints of such studies and the important data the DIS does obtain, the concern with diagnostic reliability should preclude the use of the DIS in settings where other structured diagnostic interviews can be used (e.g., the SADS or SCID).

4.05.2.8 Composite International Diagnostic Interview

The Composite International Diagnostic Interview (CIDI; Robins et al., 1988; World Health Organization [WHO], 1990) was developed at the request of WHO and the United States Alcohol, Drug Abuse, and Mental Health Administration. The CIDI was designed to serve as a diagnostic instrument in cross-cultural epidemiological and comparative studies of psychopathology. The initial version of the CIDI was based on the DIS, to cover DSM-III diagnoses, and initially incorporated aspects of the PSE since the PSE has been used in cross-cultural studies and reflects European diagnostic traditions. Some items from the DIS were altered either to provide further information for the PSE or to address language and content that would allow cross-cultural use. Additional questions were added to provide adequate coverage of the PSE-9. These PSE items were rewritten into the closed-ended format of the DIS.

Initial versions of the CIDI provided *DSM-III* diagnoses and updated versions, used in Phase II WHO field trials, now provide *DSM-III-R* and *ICD-10* diagnoses (WHO, 1990). The latest version of the CIDI has also eliminated all questions that are not needed for *DSM-III-R* (deletion of Feighner and RDC criteria) and has added items to assess *ICD-10* criteria. Furthermore, the PSE approach was abandoned and only same questions from the PSE were retained because they were relevant to *ICD-10* diagnoses. Revisions of the CIDI to meet *DSM-IV* criteria are in progress. A Substance Abuse Module was developed for the CIDI to be used alone or substituted for the less detailed coverage of drug abuse in the CIDI proper (Cottler, 1991). Other modules that have been developed or are under development include post-traumatic stress disorders, antisocial disorder, conduct disorder, pathological gambling, psychosexual dysfunctions, neurasthenia, and persistent pain disorder (Wittchen, 1994).

Like the DIS, the CIDI was intended to be used by lay interviewers with modest training (one week), and to be capable of rapid administration. In a multicenter study conducted in 15 countries the CIDI was found to be judged appropriate by the majority of interviewers (Wittchen et al., 1991). However, 31% of interviewers rated parts of the CIDI as inappropriate, in particular sections for schizophrenia and depression. The CIDI also takes a long time to administer: one-third of the interviews took one to two hours and another third lasted two to three hours (Wittchen et al., 1991). In this study the duration of the interviews may have been extended because of the assessment of predominantly clinical populations. One might expect briefer administration times with general population samples.

As with the DIS, training for the CIDI can be conducted in five days. No professional experience is necessary as the CIDI is intended to be used by lay interviewers. Training sites participating in the WHO field trials may be available to conduct courses. However, there is a CIDI user manual, a standardized training manual with item-by-item specifications, and computer scoring program available from WHO (1990).

4.05.2.8.1 Reliability

In an evaluation of the "prefinal" version of the CIDI (*DSM-III* and PSE) across 18 clinical centers in 15 countries, Wittchen et al. (1991) found high inter-rater agreement. Kappas for diagnoses were all 0.80 or greater with the exception of somatization (0.67). Wittchen (1994) has summarized test–retest reliability of the CIDI across three studies involving independent interviews conducted within a period of three days. Kappa coefficients for *DSM-III-R* diagnoses were all above 0.60 with the exception of bipolar II (0.59), dysthymia (0.52), and simple phobia (0.59).

Two studies have also examined the concordance between the CIDI and clinical ratings. Farmer, Katz, McGuffin, and Bebbington (1987) evaluated the test–retest concordance between CIDI PSE-equivalent items obtained by a lay interviewer and PSE interviews conducted by a psychiatrist. Interviews were conducted no more than one week apart. Concordance at the item level was unacceptably low. Of 45 PSE items, 37 (82%) achieved kappas below 0.50. Agreement was somewhat higher at the syndrome level but remained low for the syndromes of behavior, speech, and other syndromes (Spearman $r = 0.44$) and specific neurotic syndromes (Spearman $r = 0.35$).

Janca, Robins, Cottler, and Early (1992) examined diagnostic concordance between a clinical interviewer using the CIDI and a psychiatrist in a small sample of patients and nonclinical subjects ($N = 32$). Psychiatrists asked free-form questions and completed an *ICD-10* checklist following either the observation of lay-administered CIDI interview, or following their own administration of the CIDI. Overall diagnostic agreement appeared adequate with an overall kappa of 0.77. High concordance was also found for the *ICD-10* categories of anxiety/phobic disorders ($K = 0.73$), depressive disorders ($K = 0.78$), and psychoactive substance use disorders ($K = 0.83$).

4.05.2.8.2 Summary

The CIDI may be considered the next step beyond the DIS. This instrument incorporated lessons learned from the development of the DIS and has been subject to repeated revisions to enhance its reliability and cross-cultural application. The CIDI appears to have achieved somewhat better reliability than the DIS and it covers the latest diagnostic standards of *ICD-10* and *DSM-III-R* (soon to cover *DSM-IV*). However, the concordance between CIDI-obtained diagnoses and diagnoses obtained by other structured interviews administered by clinicians (e.g., SADS, SCID) remains unclear.

4.05.3 PERSONALITY DISORDERS

4.05.3.1 Structured Interview for *DSM-IV* Personality Disorders

Introduced in 1983, the Structured Interview for *DSM-III* Personality Disorders (SIDP) was the first structured interview to diagnose the full range of personality disorders in *DSM-III* (Stangl, Pfohl, Zimmerman, Bowers, & Corenthal, 1985). Subsequent versions have addressed Axis II criteria for the *DSM-III-R* (SIDP-R; Pfohl, Blum, Zimmerman, & Stangl, 1989) and the *DSM-IV* (SIDP-IV; Pfohl, Blum, & Zimmerman, 1995).

SIDP-IV is organized into 10 topical sections: Interests and Activities, Work Style, Close Relationships, Social Relationships, Emotions, Observational Criteria, Self-perception, Perception of Others, Stress and Anger, and Social Conformity. This format is intended to provide a more conversational flow and is thought to enhance the collection of information from related questions and facilitate the subsequent scoring of related criteria.

The SIDP-IV can be administered to a patient and to an informant, requiring 60–90 and 20–30 minutes, respectively (Pfohl et al., 1995). In addition, the interview takes 20–30 minutes to score. Each page of the interview provides questions, prompts, diagnostic criteria, and scoring anchors. The informant interview is composed of a subset of questions from the patient interview. Two alternate versions of the SIDP-IV are available. The SIDP-IV Modular Edition is organized by personality disorders rather than by topical sections. This modular form permits the interviewer to focus on disorders of interest and to omit others. The Super SIDP is an expanded version that includes all questions and criteria necessary to assess *DSM-III-R*, *DSM-IV*, and *ICD-10* personality disorders.

Several instructions for administering the SIDP-IV are noteworthy. First, the SIDP uses a "five year rule" to operationalize criteria involving an enduring pattern that represents personality. Thus, "behavior, cognititions, and feelings that have predominated for most of the last five years are considered to be representative of the individual's long-term personality functioning" (Pfohl et al., 1995, p. ii). The SIDP-IV is intended to follow assessment of episodic (Axis I) disorders in order to assist the interviewer in ruling out the influence of temporary states of behavior described by the patient. Second, the patient's responses are not given a final rating until following the interview. This is intended to allow for all sources of information to be reviewed before rating. However, unlike previous versions of the SIDP, the SIDP-IV now provides a rater with the opportunity to rate or refer to specific *DSM-IV* criteria associated with each set of questions. Third, use of an informant is optional and Pfohl et al. (1995) note that while the frequency of personality diagnoses may increase with the use of informants there appears to be little effect on predictive validity.

Each diagnostic criterion is scored as one of the following: 0 = not present or limited to rare isolated examples, 1 = subthreshold: some evidence of the trait but it is not sufficiently pervasive or severe to consider the criterion present, 2 = present: criterion is present for most of the last five years (i.e., present at least 50% of the time during the last five years), and 3 = strongly present: criterion is associated with subjective distress or some impairment in social or occupational functioning or intimate relationships. Unlike other personality interviews (e.g., the IPDE and SCID-II), scores of both 2 and 3 count towards meeting diagnostic criteria (Pilkonis et al., 1995).

The SIDP-IV is an interview requiring clinical skill in determining the need for additional probe questions and to discriminate between personality (Axis II) disorders and episodic (Axis I) disorders. The developers of the SIDP-IV recommend one month of intensive training to administer the interview properly (Pfohl et al., 1995; Standage, 1989). Pfohl et al. (1995) have reported success with interviewers having at least an undergraduate degree in the social sciences and six months of previous experience with psychiatric interviewing. Training videotapes and workshops are available from the developers of the SIDP-IV.

4.05.3.1.1 Reliability

Several investigations of inter-rater reliability reveal poor to good agreement. Using the SIDP-R, Pilkonis et al. (1995) found that inter-rater agreement for continuous scores on either the total SIDP-R score or scores from Clusters A, B, and C, was satisfactory (ICCs ranging from 0.82 to 0.90). Inter-rater reliability for presence or absence of any personality disorder with the SIDP-R was moderate with a kappa of 0.53. Due to infrequent diagnoses, mixed diagnoses, and the number of subthreshold protocols, in this study kappas for individual diagnoses were not provided.

Stangl et al. (1985) conducted SIDP interviews on 63 patients (43 interviews were conducted jointly, and 20 interviews were separated by up to one week). The kappa for presence or absence of any personality disorder was 0.66. Only five personality disorders occurred with enough frequency to allow kappa to be calculated: dependent (0.90), borderline (0.85), histrionic (0.75), schizotypal (0.62), and avoidant (0.45). Using the SIDP among a small sample of inpatients, Jackson, Gazis, Rudd, & Edwards (1991) found inter-rater agreement to be adequate to poor for the five specific personality disorders assessed: borderline ($K = 0.77$), histrionic (0.70), schizotypal (0.67), paranoid (0.61), and dependent (0.42).

The impact of informant interviews on the diagnosis of personality disorders and inter-rater agreement for the SIDP was assessed by Zimmerman, Pfohl, Stangl, and Corenthal (1986). Inter-rater agreement (kappa) for the presence or absence of any personality disorder was 0.74 before the informant interview and 0.72 after the informant interview. Kappas for individual personality disorders were all 0.50 or above. Reliability did not appear to benefit or be compromised by the use of informants. However, the informant generally provided additional information on pathology and, following the informant interview, diagnoses that had been established with the subject only were changed in 20% of the cases (Zimmerman et al., 1986).

In an examination of the long-term test–retest reliability of the SIDP, Pfohl, Black, Noyes Coryell, and Barrash (1990) administered the SIDP to a small sample of depressed inpatients during hospitalization and again 6–12 months later. Information from informants was used in addition to patient interviews. Of the six disorders diagnosed three had unacceptably low kappas (below 0.50): passive-aggressive (0.16), schizotypal (0.22), and histrionic (0.46). Adequate test–retest reliability was obtained for borderline (0.58), paranoid (0.64), and antisocial (0.84).

4.05.3.1.2 Summary

The SIDP-IV represents the latest version of the first interview to assess the spectrum of

DSM personality disorders. Although originally developed to be administered in a topical format to assess *DSM* personality disorders the SIDP-IV now provides alternative formats for assessing specific disorders without administering the entire SIDP-IV and for assessing *ICD* diagnoses. Reliability data are encouraging for some disorders. However, these data are limited to selected disorders using the SIDP and reliability data have not been presented for specific disorders using the SIDP-R (Pilkonis et al., 1995). No reliability data are available for the SIDP-IV. Little data are available concerning the long-term test–retest reliability of the SIDP. The SIDP-IV does not come with a screening questionnaire to assist in identifying personality disorders that might be a focus of the interview.

4.05.3.2 International Personality Disorder Examination

The International Personality Disorder Examination (IPDE; Loranger et al., 1995), a modified version of the Personality Disorder Examination (PDE), is a semistructured interview designed to assess personality disorders in both the *DSM-IV* and *ICD-10* classification systems. The PDE was initially developed in the early 1980s to assist in the diagnosis of personality disorders. At that time, only structured interviews existed that focused on Axis I mental disorders. A highly structured lay-administered interview for personality disorders was thought to be inappropriate due to the complexity of diagnostic criteria and level of inference required (Loranger et al., 1994). The first version of the PDE was completed in 1985. Beginning in 1985, international members of the psychiatric community attended several workshops to formulate an international version of the PDE, the IPDE, which was developed under the WHO, and the US Alcohol, Drug Abuse, and Mental Health Administration System. The purpose of the IPDE was to assess personality disorders in different languages and cultures.

The IPDE interview surveys behavior and life experiences relevant to 157 criteria and can be used to determine *DSM-IV* and *ICD-10* categorical diagnoses and dimensional scores of personality disorders. The IPDE is not recommended for use on individuals who are under the age of 18, agitated, psychotic, severely depressed, below normal intelligence, or severely cognitively impaired. The interview is available in the following languages: English, Spanish, French, German, Italian, Dutch, Danish, Norwegian, Estonian, Greek, Russian, Japanese, Hindi, Kannada, Swahili, and Tamil (Loranger et al., 1995).

The IPDE contains materials for determining both *DSM-IV* and *ICD-10* diagnoses. However, due to the long length of the interviews noted in the field trials (mean interview length was 2 hours, 20 minutes), the interview is distributed in two modules for each classification system. Furthermore, clinicians and researchers can easily administer specific personality modules to suit their purpose (Loranger et al., 1994).

A self-administered IPDE screening questionnaire may be administered prior to the interview in order to eliminate subjects who are unlikely to have any or a particular personality disorder. Similar to the SCID-II (described below), a corresponding low diagnostic threshold (for endorsement) is set for each question. If three or more items are endorsed for a specific personality disorder, then the interview is administered for that personality disorder.

In the attempt to establish reliable diagnoses, the IPDE interview utilizes two distinct guidelines. First, the behavior or trait must be present for at least five years to be considered an expression of personality with some manifestations (based on the disorder) occurring within the past 12 months (Loranger et al., 1995). This strict criterion is adopted to ensure the enduring nature of behavior and life experiences, and rule out transient or situational behaviors. A second guideline for the IPDE is that one criterion must be met before the age of 25. However, if an individual develops a personality disorder later in life (with no criterion exhibited prior to age 25) the IPDE provides an optional "late onset" diagnosis (Loranger et al, 1995).

The developers constructed the IPDE interview not only to be clearly organized, but to "flow" naturally. As a result, the diagnostic criteria are not ordered by cluster or disorder, but by six sections that assess major life domains: Work, Self, Interpersonal Relationships, Affects, Reality Testing, and Impulse Control. Each section begins with open-ended questions that provide a transition between sections and allow the interviewer to gather general background information. Closed-ended and elaboration questions follow for each criterion (Loranger et al., 1995). Each individual page of the IPDE is designed to optimally assist the interviewer in correctly determining if the diagnostic criteria is met. Each page contains: personality disorder and criterion number, structured questions, reprinted *DSM-IV* or *ICD-10* criteria, notes on determining criteria, descriptions of scoring criteria, and scoring areas for both interview and informants.

The scoring of the IPDE interview is similar to other semistructured interviews. Prior to the interview, the developers recommend that collecting information or conducting interviews on Axis I disorders be completed to assist in scoring the criteria. Each trait or behavior (i.e., criterion) is scored as one of the following: absent or normal (0), exaggerated or accentuated (1), criterion level or pathological (2), and interviewee is unable to furnish adequate information (?). Some items may not be applicable to all interviewees and scored not applicable. The IPDE also allows the interviewer to rate each criterion based on informants (Loranger et al., 1995). The IPDE manual provides information on the scope and meaning of each criterion, and provides guidelines and anchor points for scoring. The manual does not recommend challenging the interviewee on inconsistencies with informants during the interview, due to the potential threat to rapport. However, challenging discrepancies occurring within the interview is encouraged. The IPDE may be hand scored or computer scored (program provided by publishers). Hand-scored algorithms and summary sheets are provided to assist in determining categorical diagnoses and dimensional scores.

The IPDE developers recommend that only those with the clinical experience and training to make psychiatric diagnoses independently use the IPDE (Loranger et al., 1994). The IPDE manual strongly discourages the use of IPDE by clinicians early in their training, research assistants, nurses, medical students, and graduate students. In addition, the interviewer should have familiarity with the *DSM-IV* and *ICD-10* classification systems (Loranger et al., 1995). The test manual recommends the following training: read the interview and manual thoroughly, practice on several participants to get familiar with the interview, administer with an IPDE-experienced interviewer, and discuss any problems in administration or scoring. Before administering the IPDE, the interviewer should have thorough knowledge of the scope and meaning of each criterion and scoring guidelines. IPDE training courses are offered at the WHO training centers.

4.05.3.2.1 Reliability

The IPDE field trial conducted in 11 countries and 14 centers evaluated inter-rater reliability in joint interviews as well as test–retest reliability with an average test–retest interval of six months (the test–retest interviews were conducted by the same interviewer). Results indicated overall weighted kappa for individual definite personality disorders to be 0.57 for the *DSM-III-R* and 0.65 for the *ICD-10* (Loranger et al., 1994). Median kappas for definite or probable personality diagnoses were 0.73 for *DSM-III-R* and 0.77 for *ICD-10*. Using broader definite or probable criteria, kappa for any personality disorder increased to 0.70 for *DSM-III-R* and 0.71 for *ICD-10*. For temporal stability, kappas for the presence or absence of a personality disorder were 0.62 for *DSM-III-R* and 0.59 for *ICD-10*. Inter-rater reliability was higher for dimensional scores with ICCs ranging from 0.79 to 0.94 for the *DSM-III-R* and 0.86 to 0.93 for the *ICD-10*. Temporal stability for dimensional scores was also high with ICCs ranging from 0.68 to 0.92 for *DSM-III-R* and from 0.65 to 0.86 for *ICD-10*.

Pilkonis et al. (1995) also evaluated the reliability of the third version of the PDE. Intraclass correlations for total scores or cluster scores ranged from 0.85 to 0.92. Inter-rater agreement (kappa) for the presence or absence of any personality disorder was 0.55.

Loranger et al. (1991) examined inter-rater agreement and test–retest reliability of the PDE in a sample of psychiatric inpatients. Second administrations of the PDE were conducted one week to six months later by a separate interviewer blind to the initial assessment. Inter-rater agreement between two raters was assessed at both the initial and repeated interview. At the first interview kappas for inter-rater reliability ranged from 0.81 to 0.92 (median = 0.87). At the repeat interview kappas for inter-rater reliability ranged from 0.70 to 0.95 (median = 0.88). At follow up there was a significant reduction in the number of criteria met on all disorders except schizoid and antisocial. Stability of the presence or absence of any personality disorder was moderated with a kappa of 0.55.

O'Boyle and Self (1990) interviewed 20 patients with a depressive disorder for a personality disorder. Eighteen patients were re-interviewed across a mean of 63 days for the presence or absence of personality disorder. Intraclass correlations were 0.89 to 1 and inter-rater agreement (kappa) was 0.63. Depressive disorders did not consistently affect categorical diagnoses, but dimensional scores were higher during depressed periods.

4.05.3.2.2 Summary

The IPDE has a number of strengths to recommend its use. First, the IPDE (and PDE) has demonstrated medium to high inter-rater agreement and temporal reliability for both categorical diagnoses and dimensional scores. In addition, preliminary investigations into the influence of Axis I disorders (e.g. depression) on the assessment of personality disorders indicate no significant influence on PDE categorical diagnoses. Second, a detailed training manual accompanies the interview, which provides thorough instructions and scoring algorithms. Third, a unique feature of the IPDE is dual coverage of the *DSM-IV* and *ICD-10* criteria. Fourth, in addition to providing categorical diagnoses, the IPDE measures dimensional scores which provide information about accentuated normal traits below the threshold required for a personality disorder. Finally, the IPDE is available in several languages and has been studied in 11 countries.

The IPDE, while quite comprehensive, is flexible enough to permit more economical administration. The *DSM-IV* and *ICD-10* modules can be administered separately. Furthermore, rather than administer in thematic organization, the IPDE can be limited to diagnostic modules of interest. A self-administered screening questionnaire is available to assist in identifying personality disorders that might be of focus in the interview.

Inter-rater agreement between the SCID-II and IPDE have led some researchers to conclude that the IPDE (and PDE) presents more stringent guidelines to fulfill personality disorder criteria (Hyler, Skodol, Kellman, Oldhan, & Rosnik, 1990; Hyler, Skodol, Oldham, Kellham, & Doldge, 1992; O'Boyle & Self, 1990). This stringent determination is probably due to the consistent five-year time period requirement for personality traits. In conclusion, the specificity of the instrument is increased (fewer false positives) but this may be at the cost of decreased sensitivity (more false negatives).

4.05.3.3 Structured Clinical Interview for *DSM-IV* Personality Disorders

The Structured Clinical Interview for *DSM-IV* Personality Disorders (SCID-II) is a structured interview that attempts to provide an assessment of the 11 *DSM-III-R* personality disorders, including the diagnosis of self-defeating personality disorder, which is included in Appendix A of *DSM-III-R* (First, Spitzer, Gibbon, & Williams, 1995). The SCID-II interview can be used to make categorical or dimensional personality assessments (based on the number of items judged present). The SCID-II was developed as a supplementary module to the SCID-I, but was redesigned in 1985 to be a separate and autonomous instrument due to different assessment procedures and length of interview (First et al., 1995).

In conducting the SCID-II, it is extremely important to evaluate the interviewee's behavior out of the context of an Axis I disorder (Spitzer et al., 1990). The test developers recommend an evaluation of Axis I disorders prior to the SCID-II with either a SCID-I or some other Axis I evaluation.

A self-report screening questionnaire is provided to improve time efficiency. Each of the 113 items on the questionnaire corresponds to a diagnostic criterion and is purposefully constructed to have a low threshold for a positive response, and is therefore for screening purposes only. Interviewers should probe all items coded "yes" in the questionnaire. Under most circumstances, the interviewer does not need to interview for the negatively endorsed criteria, due to the low probability of psychopathology. Negative questionnaire responses should be followed up when either the interviewer suspects that the criterion or personality disorder is actually present or when the number of items endorsed positively in the interview is only one item below that required for making a diagnosis (in which case all questions for that diagnosis should be probed).

Utilizing the screening questionnaire, the SCID-II interview can usually be administered in 30–45 minutes (First et al., 1995). First, Spitzer, Gibbons, Williams, Davies, et al. (1995) interviewed 103 psychiatric patients and 181 nonpatients, and calculated a mean interview time of 36 minutes. A unique feature of the SCID-II is that the interview begins with a brief overview which gathers information on behavior and relationships, and provides information about the interviewee's capacity for self-reflection. This allows the interviewer not only to establish rapport, but also allows interviewees to provide a description and consequences of their behavior in their own words (Spitzer et al., 1990). Following the overview, the interview progresses through each relevant disorder.

The format and structure of the SCID-II is very similar to that of the SCID for Axis I disorders. Each page of the interview contains questions, reprinted *DSM-IV* criteria, guidelines for scoring, and space for scores (Spitzer et al., 1990). Initial questions are open-ended and followed up with prompts for elaboration and examples. If further clarification is needed, the interviewer is encouraged to ask supplementary (their own) questions, give examples, present hypothetical situations, and challenge inconsistencies (Spitzer et al., 1990). There are usually two to three interview questions for each personality disorder criterion. In essence, the interviewer is testing diagnostic hypotheses. The ratings are based not on the question response, but an fulfillment of *DSM-IV* criteria. The interviewer is encouraged to use alternate sources of information to assist in rating the criteria, such as observed behavior, medical records, and informants. With slight modifications, the SCID-II can be administered to an informant (First et al., 1995). Each criterion is rated as one of the following: ? = inadequate information, 1 = symptom clearly absent or criteria not met, 2 = subthreshold condition that almost meets criteria, and 3 = threshold for criteria met.

A rating of "3" is scored only when the interviewee provides convincing, elaborative, and/or exemplary information. A rating of "3" is reserved only for criteria that fulfill the following three guidelines: pathological (outside normal variation), pervasive (occurs in a variety of places and/or with a variety of people), and persistent (occurs with sufficient frequency over at least a five-year period). Specific guidelines for a "3" rating are provided for each criterion in the body of the interview.

Due to the similarity in interview procedures, SCID-II training procedures are almost identical to SCID-I training. As with the SCID-I, clinical judgment is required in the administration and scoring of the SCID-II and thus requires interviewers to have a full understanding of *DSM* nosology and experience in diagnostic interviewing. A user's manual is available for the SCID-II and demonstration videotapes are available. Training workshops can also be arranged with the developers.

4.05.3.3.1 Reliability

The test–retest reliability of the SCID-II was examined within an investigation of the reliability of the Axis I SCID (Williams et al., 1992). In this study, First, Spitzer, Gibbons, Williams, Davies, et al. (1995) administered the SCID-II to 103 psychiatric patients and 181 nonpatients. Two raters independently administered the SCID-II between 1 and 14 days apart. Each SCID-II was preceded by an Axis I SCID evaluation. The SCID-II Personality Questionnaire was given only on the occasion of the first assessment (both SCID-II interviews used the same questionnaire results). Overall weighted kappas were 0.53 and 0.38 for patients and nonpatients, respectively. For the patient sample, kappas were above 0.5 for avoidant, antisocial, paranoid, histrionic, and passive-aggressive personality disorders, and below 0.5 for dependent, self-defeating, narcissistic, borderline, and obsessive-compulsive personality disorders. For the nonpatient sample, kappas were above 0.5 for dependent, histrionic, and borderline personality disorders, and below 0.5 for avoidant, obsessive-compulsive, passive-aggressive, self-defeating, paranoid, and narcissistic personality disorders.

Using the Dutch version of the SCID-II, Arntz et al. (1992) randomly selected 70 mental health center outpatients and conducted SCID-II interviews. Inter-rater reliability was determined by comparing criteria scores between a primary interviewer and an observer. With the exception of a few criteria, inter-rater reliability for each criterion was good to excellent. Eighty-four of 116 *DSM-III-R* criteria had ICCs higher than 0.75, and 14 had reliability ranging from 0.60 to 0.75. Inter-rater reliability was not able to be rated for 12 criteria due to lack of variance. Inter-rater agreement for specific personality disorders was good with kappas ranging from 0.65 to 1.

Several other studies report good to excellent inter-rater reliability and agreement using the SCID-II (Brooks, Baltazar, McDowell, Munjack, & Bruns, 1991; Fogelson, Nuechterlein, Asarnow, Subotnik, & Talovic, 1991; Malow, West, Williams, & Sutker, 1989; Renneberg, Chambless, & Gracely, 1992). However, these studies contained two or more of the following limitations: restricted number of personality disorders, a homogeneous population and a small number of participants.

4.05.3.3.2 Summary

The SCID-II differs from other personality interviews in several respects. Although other interviews have a disorder-based format available, only the SCID-II has this format as its primary (and only) format of administration. First et al. (1995) maintain that the grouping of questions based on disorder may more closely approximate clinical diagnostic practice and that this grouping forces interviewers to consider criteria in the context of the overarching theme of the disorder. One disadvantage is that the lack of a thematically organized format limits an interviewer's choices, and some have raised concerns that disorder-based organization results in redundancy and repetition with similar items across different diagnoses. Also, the organization of items by disorder may create "halo" effects where a positive criterion rating may bias an interviewer's rating of similar items.

Although the SCID-II screening questionnaire is unusual the IPDE now has a screening questionnaire as well (neither the SIDP-IV or the PDI-IV use screening questionnaires). The SCID-II has shown reliability comparable to other interviews and has been used in a number of studies. The shared format between the SCID-II and the SCID for Axis I disorders should facilitate training on the two measures and may ease the typical requirement that Axis I disorders are assessed and taken into consideration when conducting personality disorder examinations.

4.05.3.4 Personality Disorder Interview-IV

The Personality Disorder Interview-IV (PDI-IV; Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995) is a semistructured interview developed to assess 10 *DSM-IV* personality disorders as well as the two *DSM-IV* personality criteria sets provided for further study (depressive personality disorder, passive-aggressive personality disorder). The PDI-IV is the fourth edition of the Personality Interview Questionnaire (PIQ). The name change was based, in part, on the intent to provide a more descriptive title as the PDI focuses on the assessment of disordered personality.

The PDI-IV provides questions for the assessment of the 94 diagnostic criteria that relate to the 12 *DSM-IV* personality disorders. Criterion ratings are made on a three-point scale (0 = not present, 1 = present according to *DSM-IV* criteria, 2 = present to more severe or substantial degree). Questions from the PDI-IV were selected as useful in determining criterion ratings and additional questions are provided for further elaboration if time allows. However, given the questionnaire's semistructured format, the interviewer may deviate from questions to obtain further information or to address inconsistencies. It is suggested that all positive responses be followed by a request for examples.

The PDI-IV can be administered in a manner either organized by thematic content (as with the IPDE and SIDP) or by *DSM-IV* diagnostic category (as with the SCID-II). Separate interview booklets are provided for these two forms of administration. For occasions when all personality disorders will be assessed, it is recommended that the thematic administration be used. Content areas in the thematic format include Attitudes Towards Self, Attitudes Toward Others, Severity or Comfort with Others, Friendships and Relationships, Conflicts and Disagreements, Work and Leisure, Social Norms, Mood, and Appearance and Perception. The diagnostic format may be preferable when only particular disorders must be assessed. Ratings can be used either to derive categorical or dimensional ratings for *DSM-IV* personality disorders.

The PDI-IV comes with an extensive manual that discusses general issues regarding administration but also provides a thorough discussion of each personality disorder in separate chapters. Each chapter provides an overview of the history and rationale for the personality disorder including discussion of the development of the criterion in *DSM* as well as *ICD* and other criterion sets. Each criterion item is discussed with regard to revisions and rationale for each item, ratings and questions, and issues and problems relevant to assessing that criterion.

The PDI-IV does not include the use of a self-report questionnaire. However, Widiger et al. (1995) do recommend that a stand-alone self-report inventory be used to assess personality. Scores from such a questionnaire may then be used to inform selection of the most relevant personality disorders to assess on the PDI-IV. Widiger et al. (1995) suggest that the use of such self-report measures will serve the same purpose as screening questionnaires but also will provide more information than measures simply designed for screening purposes.

The PDI-IV manual indicates that, although lay interviewers can administer the PDI-IV, extensive training and supervision is required. Even then, it is recommended that final item scoring be done by an experienced clinician. Ideally, the PDI-IV should be administered and scored by a professional clinician with training and experience in diagnosis and assessment. The PDI-IV manual outlines suggested training beginning with study of the *DSM-IV*, articles on the diagnosis or assessment of personality disorders, and the PDI-IV manual and interview booklets. Following discussion of this literature it is recommended that trainees conduct pilot interviews with nonclinical subjects. Tapes of these initial interviews should be reviewed and feedback provided. It is then suggested that 5–10 patient interviews be conducted and taped for review. Continued taping and systematic review of interviews is recommended to avoid interviewer drift.

4.05.3.4.1 Reliability

Inter-rater agreement for presence vs. absence of personality disorders ranges from 0.37 (histrionic) to 0.81 (antisocial), with a median kappa of 0.65. Agreement for the number of personality disorder criteria met ranges from 0.74 (histrionic, narcissistic, and schizotypal) to 0.90 (obsessive-compulsive and passive-aggressive) and 0.91 (sadistic). Median reliability for the number of PD criteria met was 0.84. Although these data are generally encouraging there are some concerns. Unfortunately, the population on which these reliability data were obtained is not specified nor are the methods for determining rater agreement described. More detailed information may be available from the unpublished dissertation from which these data are derived (Corbitt, 1994).

4.05.3.4.2 Summary

The PDI-IV is built upon the extensive history and experience derived from prior editions of this interview. The PDI-IV manual is one of the more extensive, thorough, and informative manuals available for the assessment of personality disorders. The flexibility afforded by the choice of either thematic content format or diagnostic category format is also attractive. Despite the accumulation of research on prior versions of the PDI-IV, there is limited reliability data for the PDI-IV. However, the PDI-IV is the only personality interview that has reliability data available for the *DSM-IV* personality disorders.

4.05.4 CHILD AND ADOLESCENT DISORDERS

4.05.4.1 Schedule for Affective Disorders and Schizophrenia for School Age Children

The Schedule for Affective Disorders and Schizophrenia for School Age Children (K-SADS; Puig-Antich & Chambers, 1978) is a semistructured interview designed for research or clinical assessment by a trained clinician. The K-SADS was developed as a child and adolescent version of SADS resulting from research in childhood depression. The K-SADS covers a wide range of childhood disorders but has a strong emphasis on major affective disorders (Roberts, Vargo, & Ferguson, 1989). The interview is intended to assess both past and current episodes of psychopathology in children aged 6–17 years old.

The K-SADS-III-R is compatible with *DSM-III-R* criteria. This version of the SADS provides 31 diagnoses within affective disorders (including depression, bipolar disorder, dysthymia, and cyclothymia), eating disorders, anxiety disorders, behavioral disorders (e.g., conduct disorder, substance abuse/dependence), psychoses, and personality disorders (i.e., schizotypal and paranoid)

The K-SADS is composed of three parts. It begins with an unstructured interview that aims to put the patient at ease and gather information regarding present problems, onset and duration of problems, and treatment history. Following this general interview, the interviewer asks questions relevant to specific symptoms and diagnostic criteria. Sample questions are provided only as a guideline, and modification is encouraged. If initial probe questions are negative, follow-up questions are skipped over. At the conclusion of the interview, observational items are rated (Roberts et al., 1989).

The parent interview should be conducted first, followed by the child interview. The child and parent interview require approximately 90 minutes each. The K-SADS focuses on the last week and most intense symptoms over the last 12 months. Each time period is rated independently and a summary score is made. Diagnostic criteria are rated as present or absent, and then rated on severity (Ambrosini, Metz, Prabucki, & Lee, J., 1989). Ultimately, diagnoses are given based on clinical judgment (Hodges, McKnew, Burbach, & Roebuck, 1987).

As with the SADS, the K-SADS requires extensive training and experience in psychiatric interviewing but has an added burden of conducting interviews with adults (parent/guardian) and children. Full familiarity with *DSM-III-R* is required. Training typically requires viewing videotapes and the conduct of practice interviews with ongoing supervision.

4.05.4.1.1 Reliability

Chambers et al. (1985) examined test–retest reliability of the K-SADS administered to children and parents. Test–retest reliability of major diagnoses was generally adequate with kappas ranging from 0.54 to 0.74, with the exception of anxiety disorder ($K = 0.24$). Individual symptoms and symptom scales generally showed adequate test–retest reliability with anxiety-related symptoms showing the lowest reliability. Agreement between the parent and child interviews varied greatly, ranging from poor to excellent. This later finding suggests the nonredundant aspect of these two interviews.

Inter-rater reliability was examined in videotaped K-SADS-III-R interviews by Ambrosini, et al. (1989). Inter-rater agreement among child, parent, combined interview ratings, and across time frames (present episode and last week) ranged from acceptable ($K = 0.53$) to excellent ($K = 1$) for major depression, minor depression, overanxious disorder, simple phobia, separation anxiety, oppositional, and attention deficit. Of the 36 kappa values, 30 were 0.75 or higher.

Apter, Orvaschel, Laseg, Moses, and Tyano (1989) examined inter-rater and test–retest agreement in a sample of adolescent inpatients (aged 11 to 18 years). Overall inter-rater and test–retest agreement was high with kappas of 0.78. Reliability of symptom scales was also adequate with ICCs of 0.63–0.97 for inter-rater agreement and ICCs of 0.55–0.96 for test–retest agreement. Diagnostic agreement between parent and child interviews (conducted by different clinicians for each informant) was generally low with an overall kappa of 0.42. Parent–child agreement for symptom scales was particularly low for anxiety symptoms.

4.05.4.1.2 Summary

The K-SADS extensively covers the major affective disorders and has adequate coverage of other childhood disorders. It has been one of the main diagnostic interviews available for use with children and adolescents. Reliability data are very positive for a number of disorders. However, reliability data are largely for *DSM-III* diagnoses and limited data are available for *DSM-III-R* diagnoses (no data are available for *DSM-IV*).

4.05.4.2 Child Assessment Schedule

The Child Assessment Schedule (CAS; Hodges, Kline, Stern, Cytryn, & McKnew, 1982) is a structured interview that is unique in that it is modeled after traditional clinical interviews with children. The interview is organized around thematic topics (e.g., school, friends) with diagnostic items inserted within these topics. Structured questions are provided in a format that is intended to develop rapport. Hodges (1993) has noted that about half of the CAS material related to clinical content does not reflect directly on diagnostic criteria.

The CAS is organized into three parts. In the first part 75 questions are organized into 11 content areas: school, friends, activities and hobbies, family, fears, worries, self-image, mood, somatic concerns, expression of anger, and thought disorder symptoms. Items are rated true (presence of symptom), false (absence of symptom), ambiguous, no response, or not applicable. In the second part the onset and duration of symptoms is assessed. In the third part of the CAS, following completion of the interview, 56 items are rated based on observations during the interview. These items include the following areas: insight, grooming, motor coordination, activity level, other spontaneous physical behaviors, estimate of cognitive ability, quality of verbal communications, quality of emotional expression, and impressions about the quality of interpersonal interactions. A parallel form of the CAS is available for administration to parents (P-CAS). The same inquiries are made, with parents being asked about the child.

Quantitative scales can be obtained for a total score, scores for content areas and for symptom complexes. The internal consistency of the scale scores has been examined and are generally adequate with a few exceptions. Symptom scales have been found to be internally consistent (Hodges, Saunders, Kashani, Hamlett, & Thompson, 1990), especially in a psychiatric sample with some attenuation in medically ill and community samples (particularly for anxiety symptoms). Hodges and Saunders (1989) examined the internal consistency of content scales for both the CAS and P-CAS. For the CAS, content scales generally had alphas greater than 0.70 but low internal consistency was found for Activities and Reality Functioning. For the P-CAS, content scales with alphas below 0.60 were Activities, Reality-testing Symptoms, Self-image, and Fears. Diagnoses for *DSM-III-R* can be derived in addition to these scale scores. The CAS takes approximately 45 minutes to one hour to complete.

It is recommended that the CAS be administered by trained clinicians (although lay interviewers have been used; Hodges et al., 1987). Guidelines for administering, scoring, and interpreting the CAS are contained in the CAS manual (Hodges, 1985) and in guidelines established for achieving rater reliability (Hodges, 1983).

4.05.4.2.1 Reliability

In the initial rater reliability study, Hodges, McKnew, Cytryn, Stern and Kline (1982) examined inter-rater agreement using videotaped interviews. For symptom scores, mean kappas were generally close to or exceeded 0.60. Mean correlations across raters for content areas was 0.63 or above with the exception of worries (0.59). For symptom complexes mean correlations were 0.68 or above except for attention deficit without hyperactivity (0.58), separation anxiety (0.56), and socialized conduct (0.44). Hodges et al. (1982) also report inter-rater reliability on a small sample ($N = 10$). Correlations for items, content scores, and symptom complex scores were all above 0.85. Verhust, Althaus, and Berden (1987) also have reported inter-rater reliability for contents scores using a small number ($N = 10$) of videotaped interviews. Correlations for content areas ranged from 0.70 to 0.97.

In the only test–retest reliability study of the CAS, Hodges, Cools, and McKnew (1989) examined agreement over a mean of five days with an inpatient sample. Intraclass correlations indicated good reliability for the total CAS score and scale scores. Kappas for *DSM-III* diagnoses of conduct disorder, depression, and anxiety were above 0.70. However, the kappa for attention deficit disorder was only 0.43.

The concordance between the CAS and the K-SADS was examined by Hodges et al. (1987). Lay interviewers were used and agreement was examined for both child and parent interviews for four major diagnostic categories (attention deficit disorder, conduct disorders, anxiety disorders, and affective disorders). Only present episodes were evaluated. Child only diagnostic concordance between the CAS and K-SADS was poor for attention deficit disorder and anxiety disorders (kappas less than 0.40). Better agreement was obtained for parent only interviews or in combinations of child and parent interviews. Anxiety disorders generally had low concordance across informant conditions.

The concordance between child and parent interviews has also been examined with the CAS. Verhulst et al. (1987) found low to moderate correlations between parent- and child-derived content areas, somatic concerns, and observational judgments. Of 22 correlations, only four exceeded 0.40. The total score correlation was 0.58, indicating approximately 34% shared variance. Hodges, Gordon, and Lennon (1990) also found low to moderate correlations between parent and child interview ratings. For diagnostic areas, the lowest correlations (those below 0.30) were obtained for overanxious disorder, oppositional disorder, and separation anxiety. Low correlations (again below 0.30) were also found in the content areas of fears, worries and anxieties, and physical complaints. These data indicate reasonable parent–child agreement for conduct/behavioral problems, moderate agreement for affective symptoms, and low agreement for anxiety symptoms. As with other child assessment measures, the greatest parent–child agreement appears to be for observable behavior and the lowest for subjective experiences (Hodges et al., 1990; Hodges, 1993).

4.05.4.2.2 Summary

The CAS appears to provide a reliable assessment of a range of symptoms and shows reasonable convergence with noninterview measures. It does not cover a number of disorders including sleep disorders, eating disorders, alcohol or drug use disorders, or mania. Although it provides a broad clinical assessment, some users may find that the presence of many CAS items that do not reflect directly on diagnostic criteria is inefficient. Inter-rater agreement for diagnoses studied appears adequate. However, only one small-scale study has examined test–retest reliability for a subset of diagnoses. No reliability data are available for *DSM-IV* diagnoses.

4.05.4.3 Child and Adolescent Psychiatric Assessment

The Child and Adolescent Psychiatric Assessment (CAPA; Angold et al., 1995) was developed in order to assess a wide range of diagnostic classifications including *DSM-III*, *DSM-III-R*, *ICD-9*, and *ICD-10*. Additionally, other symptoms of clinical interest are evaluated. As with other interviews, the CAPA can be administered to children and parents. The CAPA has four sections, three of which pertain to the interview proper. The time period addressed is the three months preceding the interview. In the Introduction, the interview is conducted in a conversational manner in order to establish rapport. Questions within the Introduction address three areas: home and family life, school life, peer groups and spare time activities.

The second section is the Symptom Review which has a disorder-based organization. A wide range of disorders are covered including anxiety disorders, obsessive-compulsive disorders, depressive disorders, manic disorders, somatization disorders, food-related disorders, sleep disorders, elimination disorders, tic disorders and trichotillomania, disruptive behavior disorders, tobacco use, alcohol, psychotic disorders, life events and post-traumatic stress disorder (PTSD), and drugs. Due to problems in child report with some disorders, only the parent interview assesses sleep terror disorder, sleepwalking disorder, and attention deficit hyperactivity disorder. Alternatively, because parents may be a poor source of information for children's substance use, delusions, hallucinations, and thought disorder these items are abbreviated in the parent interview with more extensive coverage in the child interview.

The third section of the interview assesses incapacity. At this point the interviewer reviews symptom information and questions about the effects of symptoms in 17 areas of psychosocial impairment. Impairment is evaluated in the three domains of home and family life, school life, peer groups and spare time activities. Finally, following the interview, observations of interview behavior are rated for 67 items. These items cover level of activity, child's mood state, quality of child's social interaction during interview, and psychotic behavior.

Detailed questions are provided for each interview item in the CAPA. There are three levels of questions. Screening questions allow a skip-out of a section. If the screen question is positive two levels of probes are provided. Emphasized probes are required and should be asked for all subjects. Discretionary probes are provided if further information is required. A glossary is provided to be used in conjunction with the standardized questions. The glossary provides operational definitions of symptom items. These definitions were based on a review of several of the existing clinical child interviews. The glossary also provides explicit rating principles including a formal definition of the item, ratings of intensity (from 0, absent, to 3, present at a higher intensity level), duration, length of time symptom is occurring, and psychosocial impairment related to the symptom.

A wealth of information is obtained with the CAPA. Fortunately, a computer program is available in order to summarize these data with a series of diagnostic algorithms (the CAPA Originated Diagnostic Algorithms; CODA). The CODA can generate diagnoses according to *DSM-III*, *DSM-III-R*, *DSM-IV*, and *ICD-10* systems as well as symptom scores for particular diagnostic areas.

Angold et al. (1995) report that the CAPA has been used with a variety of populations (both clinical and general population) in both the UK and the USA. Training requires four to five weeks with emphasis on practice administering the CAPA and group ratings of tapes. Based on its use in multiple clinical centers explicit training criteria have been developed and details about the CAPA and its training requirements can be obtained from Angold.

4.05.4.3.1 Reliability

Angold and Costello (1995) examined test–retest reliability in a clinical sample. Interviews were conducted with children only and were completed within 11 days of each other. Kappas for specific *DSM-III-R* diagnoses were all above 0.73, with the exception of conduct disorder ($K = 0.55$). Agreement on symptom scales for these disorders was also high with ICCs above 0.60 except for conduct disorder (ICC = 0.50). No reliability data were available for a number of disorders covered in the CAPA including obsessive-compulsive disorders, manic disorders, food-related disorders, sleep disorders, elimination disorders, tic disorders, psychotic disorders, or life events and PTSD.

4.05.4.3.2 Summary

The CAPA appears to offer a thorough clinical evaluation that incorporates several diagnostic criteria. It provides a broader assessment with more contemporary diagnostic nosology than some other instruments. However, this breadth of assessment does come at a cost. The CAPA administered to the child alone can take one hour and coding can take another 45 minutes. The CAPA is not recommended for use with children under the age of eight. Additionally, the CAPA is limited to the three months preceding the interview. Although reliability data are encouraging, these data are limited to child only interviews, are not available for a number of disorders covered by the CAPA, and are not available for *DSM-IV* diagnoses. It will be important to determine the reliability of other disorders as well as that of parent interviews, and whether diagnostic agreement is improved with both child and parent administration.

4.05.4.4 Diagnostic Interview Schedule for Children

The Diagnostic Interview Schedule for Children (DISC) is a highly structured interview designed to assess most child and adolescent psychiatric disorders (Jensen et al., 1995) The interview was introduced in 1982 as a child version of the Diagnostic Interview Schedule (DIS). The DISC was intended to be administered by lay interviewers and used for epidemiological research (Shaffer et al., 1993). The version current in the late 1990s, DISC-2.1 covers 35 diagnostic criteria for the *DSM-III-R*, and contains a child (DISC-C) and parent (DISC-P) interview. The DISC was designed for children and adolescents ranging from 6 to 18 years old.

DISC interviewers are encouraged not to deviate from the order, wording, and scoring procedures. The child and parent interviews of the DISC-2.1 require approximately 60–75 minutes each (Jensen et al., 1995). Questions, organized into six separate diagnostic modules, inquire about current and past symptoms, behaviors, and emotions of most child and adolescent diagnoses. Diagnostic criteria are initially assessed with a broad "stem question" (with a low diagnostic threshold) and, if endorsed, followed with "contingent questions" to determine criteria requirements, duration, frequency, impairment, and other modifiers (Fisher et al., 1993). The DISC-2.1 focuses on the last six months and a graphic timeline is used to assist in recall (Fisher et al., 1993; Jensen et al., 1995). At the end of each module, supplementary questions are provided to assess onset, current impairment, treatment history, and precipitating stressors. Questions are rated as: "no," "yes," or "sometimes" or "somewhat," and a computer algorithm generates diagnoses.

The DISC was specifically developed for use by lay interviewers in epidemiological research. Interviewer training typically takes one to two weeks. No differences in performance have been found between clinicians and lay interviewers using the DISC-1 (Shaffer et al., 1993). A user's manual for the DISC is available.

4.05.4.4.1 Reliability

Jensen et al. (1995) examined test–retest reliability in both a clinical and community sample across three sites. In the clinic sample, for major diagnostic categories, test–retest agreement was adequate for parents (*K* range = 0.58–0.70) and was generally higher than that obtained for child interviews (*K* range = 0.39–0.86). Using a combined diagnostic algorithm, test–retest agreement was adequate (*K* range = 0.50–0.71). Inter-rater agreement was lower for the community sample with test–retest agreement lower for parents (*K* range = 0.66) and children (*K* range = 0.23–0.60). The combined diagnostic algorithm for the community sample continued to provide low agreement (*K* range = 0.26–0.64). Instances of diagnostic disagreement in the clinic sample appeared to be related to an absolute decrease in the number of symptoms at the time of the second interview. Low reliability in the community sample was attributed to decreased symptom severity, the presence of threshold cases, and other unknown factors.

Other studies have generally found adequate test–retest reliability for the DISC. One general pattern that has emerged is greater agreement when examining parent interviews. Schwab-Stone et al. (1993) interviewed 41 adolescents (aged 11–17 years) and 39 parents twice (1–3 weeks apart) with the DISC-R. Inter-rater agreement ranged from poor (*K* = 0.16) to good (*K* = 0.77) for the child interviews, and ranged from fair (*K* = 0.55) to excellent (*K* = 0.88) for the parent interviews. Schwab-Stone, Fallon, Briggs, and Crowther (1994) interviewed 109 preadolescents (aged 6–11 years) and their parents twice (7–18 days apart) with the DISC-R. Inter-rater agreement ranged from poor (*K* = 0) to fair (*K* = 0.56) for the child interviews, and from poor (*K* = 0.43) to excellent (*K* = 0.81) for the parent interviews. Based on the lower inter-rater agreement for preadolescents, Schwab-Stone et al. (1994) concluded that highly structured interviews were not appropriate for directly assessing young children due to lower endorsement of symptoms and unreliable reporting within the interview.

Most of the reliability studies on the DISC have examined only the most common childhood diagnoses and little information is available on uncommon diagnoses. From a clinical sample of relatively uncommon diagnoses, Fisher et al. (1993) interviewed 93 children (aged 8–19 years) and 75 parents with the DISC-2.1. Using the clinic diagnosis as a standard, the DISC-2.1 had good (0.73) to excellent (1) sensitivity in identifying eating disorders, major depressive disorders, obsessive-compulsive disorder, psychosis, substance use disorders, and tic disorders. The DISC-2.1 was noted to ;be less sensitive for major depressive disorder than other interviews (K-SADS, DICA, CAS).

4.05.4.4.2 Summary

The DISC's design for epidemiological research constitutes several advantages. First, the highly structured interview may be administered by nonclinicians. Second, the DISC contains the full range of disorders. Finally, the DISC has been thought to contain a lower threshold for disorders than other interviews, which makes it ideal for screening and use in the general population (Roberts et al., 1989). However, the design of the DISC has several disadvantages. It may be too restrictive, at times not allowing the interviewer to probe further and adapt the interview to accommodate special situations. The DISC has shown to be unreliable among young children and is fairly long requiring 60–75 minutes each for the two interviews. Research on the concordance between the DISC and clinical structured interviews such as the K-SADS has not been examined.

4.05.4.5 Diagnostic Interview for Children and Adolescents

The Diagnostic Interview for Children and Adolescents (DICA) is a highly structured interview designed to be used by lay interviewers for clinical and epidemiological research. The interview assesses the present episode of a wide range of psychopathology among children aged 6–17 years (Roberts et al., 1989). The interview initially appeared in 1969, and was revised in 1981 to emulate the organization of the DIS and based on *DSM-III* criteria (Welner, Reich, Herjanic, Jung, & Amado, 1987). The DICA was subsequently revised to conform to *DSM-III-R* diagnoses (DICA-R; Kaplan & Reich, 1991). In addition to coverage of *DSM-III-R*, the DICA-R was also revised so that questions were presented in a more conversational style.

The DICA-R is organized into 15 sections. Two sections cover general and sociodemographic information, 11 sections relate to disorders and symptomatology, and remaining sections address menstruation, psychosocial stressors, and clinical observations. The DICA consists of a separate parent (DICA-P) and child (DICA-C) interview. The child interview requires 30–40 minutes to administer, while the parent interview takes longer due to additional questions on developmental history, medical history, socioeconomic status, and family history (Roberts et al., 1989). For each diagnostic criterion, one or more questions elicit information. Follow-up questions are skipped if primary questions are responded negatively. Responses on the DICA-R are coded on a four-point scale: "no," "rarely," "sometimes" or "somewhat," and "yes." Following each diagnostic section, specific *DSM* criteria are listed to assist in deriving diagnoses (Welner et al., 1987).

4.05.4.5.1 Reliability

Limited data on the inter-rater agreement of the DICA is available. Only one study has provided data pertaining to individual diagnoses with an adequate description of sample and methods. Welner et al. (1987) administered two independent interviews (1–7 days apart) to 27 psychiatric inpatients (aged 7–17 years). Using lay interviewers, inter-rater agreement was excellent across diagnostic categories (K range = 0.76–1, median = 0.86).

Similar to other interviews, diagnoses derived from the parent and child interviews vary. Welner et al. (1987) examined concordance between child and parent interviews among 84 outpatients (ages 7–17 years). Fair to excellent concordance was noted (K range = 0.49–0.80, median = 0.63). However, other studies have found more modest concordance between parent and child interviews with median kappas below 0.30 (Earls, Reich, Jung, & Cloninger, 1988; Sylvester, Hyde, & Reichler, 1987).

4.05.4.5.2 Summary

The DICA-R appears to be a well-developed instrument that has taken special care in the writing and sequencing of questions. Although the DICA has been used in a number of studies, only a limited amount of reliability information is available. No reliability information is available for the DICA-R. Other child and adolescent interviews may be more attractive because of the relatively greater inter-rater reliability information.

4.05.5 SUMMARY

There has been an enormous amount of research conducted on the development and use of structured clinical interviews since the late 1960s. This research has yielded diagnostic interviews that address an array of clinical diagnoses in both adult and child populations. The use of structured interviews can not only provide reliable diagnostic evaluations but can also serve to ensure a broad and thorough clinical assessment. Although most readily embraced in research settings, it is anticipated (and hoped) that structured diagnostic interviews will become more commonplace in clinical applied settings as part of the standard assessment tools that clinicians use regularly.

4.06.1 INTRODUCTION

While treatment strategies derived from behavioral principles have a long and rich tradition in clinical child psychology (e.g., Holmes, 1936; Jones, 1924; Watson & Rayner, 1920), assessment practices based on these same principles have lagged, especially in the area of child behavioral assessment. In fact, many child behavioral assessment practices have been adopted, sometimes indiscriminately, from those used with adults. This practice is of dubious merit and, as we have argued elsewhere (Ollendick & Greene, 1990), it has frequently led to imprecise findings and questionable conclusions. As a result, greater attention has been focused on the development of behavioral assessment practices for children in recent years (e.g., Mash & Terdal, 1981, 1989; Ollendick & Hersen, 1984, 1993; Prinz, 1986).

As first suggested by Mash and Terdal (1981) and elaborated by Ollendick and Hersen (1984, 1993), child behavioral assessment can be defined as an ongoing, exploratory, hypothesis-testing process in which a range of specific procedures is used in order to understand a given child, group, or social ecology, and to formulate and evaluate specific intervention techniques. As such, child behavioral assessment is a dynamic, self-correcting process. It seeks to obtain information from a variety of sources in order that we might understand diverse child behavioral problems in their rich and varied contexts, and plan and evaluate behavioral interventions based upon the information obtained. Thus, assessment from this perspective is fluid (i.e., responsive to feedback and open to change(s) based on information obtained throughout the process), and it is linked intimately with treatment (i.e., assessment serves treatment). Moreover, child behavioral assessment entails more than the identification of discrete target behaviors and their controlling variables. While the importance of direct observation of target behaviors in simulated and natural settings should not be underestimated, recent advances in child behavioral assessment have incorporated a range of assessment procedures, including behavioral interviews, self-reports, ratings by significant others, and self-monitoring in addition to behavioral observations. An approach combining these procedures can best be described as a multimethod one in which an attempt is made to obtain a complete picture of the child and his or her presenting problems. Such a picture is intended to be useful in the understanding and modification of specific child behavior problems (Ollendick & Cerny, 1981; Ollendick & Hersen, 1984, 1993).

Two other primary features characterize child behavioral assessment procedures (Ollendick & Hersen, 1984, 1993). First, they must be sensitive to development, and second, they must be validated empirically. As noted by Lerner (1986, p. 41), the concept of development implies "systematic and successive changes over time in an organism." Descriptors such as "systematic" and "successive" suggest that these changes are, for the most part, orderly and that changes seen at one point in time will be influenced, at least in part, by changes that occurred at an earlier point in time. Thus development is not random nor, for that matter, discontinuous. Changes that occur at an early age (whether due to learning, an unfolding of basically predetermined structures, or some complex, interactive process) have a direct impact on subsequent development. Changes associated with development, however, create problems in selecting appropriate methods of assessment, as well as in identifying specific target behaviors for change (Ollendick & King, 1991). Behavioral interviews, self-reports, other-reports, self-monitoring, and behavioral observation may all be affected by these rapidly changing developmental processes. Further, due to "systematic and successive" change, some of these procedures may be more useful at one age than another. For example, interviews may be more difficult to conduct and self-reports less reliable with younger children, whereas self-monitoring and behavioral observations may be more reactive at older ages (Ollendick & Hersen, 1984). Age-related constraints are numerous and must be taken into consideration when selecting specific methods of assessment.

Just as child behavioral assessment procedures must be developmentally sensitive, they must also be validated empirically. All too frequently, professionals working with children have used assessment methods of convenience without sufficient regard for their psychometric properties, including their reliability, validity, and clinical utility (i.e., the degree to which assessment strategies contribute to beneficial treatment outcomes; see Hayes, Nelson, & Jarrett, 1987, for a discussion of treatment utility). Although child behavior assessors have fared somewhat better in this regard, they too have tended to design and use idiosyncratic, "convenient" tools for assessment. As we have suggested elsewhere (Ollendick & Hersen, 1984), comparison across studies is made difficult, if not impossible, and the advancement of an assessment science and technology, let alone an understanding of child behavior disorders and their effective treatments, is compromised with such an idiosyncratic approach.

While a multimethod approach that is based on developmentally sensitive and empirically validated procedures is recommended, it should be clear that a "test battery" approach is not being espoused. The specific devices to be selected depend on a host of factors, including the child's age, the nature of the referral question, the contexts in which the problematic behavior occurs, and the personnel, time, and resources available (Ollendick & Cerny, 1981). Nonetheless, given inherent limitations in each of the various procedures, as well as the desirability of obtaining as complete a picture of the child as possible, we recommend multimethod assessment whenever possible. Any one procedure, including direct behavioral observation, is not sufficient to provide a composite view of the child. The multimethod approach, if implemented, is not only helpful in assessing specific target behaviors and in determining response to behavior change, but also in understanding child behavior disorders and advancing assessment as a scientific endeavor. Based on these considerations, we offer the following tentative conclusions regarding child behavioral assessment:

(i) Children are a special and unique population. The automatic extension of adult behavioral assessment methods to children is not warranted and is often inappropriate. Further, not all "children" are alike. Clearly, a 16-year-old adolescent differs from a 12-year-old preadolescent who in turn differs from an 8-year-old middle-age child and a young 4-year-old child. Age-related variables affect the choice of methods as well as the procedures employed.

(ii) Given rapid developmental change observed in children as they grow, normative comparisons are required to ensure that appropriate target behaviors are selected and that change in behavior is related to treatment effects, and not normal developmental processes. Such comparisons require identification of suitable reference groups and information about the "natural course" of diverse child behavior problems (Ollendick & King, 1994).

(iii) Thorough child behavioral assessment involves multiple targets of change, including overt behavior, affective states, and cognitive processes. Further, such assessment entails determining the context (e.g., familial, social, cultural) in which the child's behavior occurs and the function(s) the target behaviors serve.

(iv) Given the wide range of targets for change and the imprecision of extant measures, multimethod assessment is desirable. Multimethod assessment should not be viewed simply as a test battery approach; rather, methods should be selected on the basis of their appropriateness to the referral question. Regardless of the measures used, they should be developmentally sensitive and empirically validated.

4.06.2 HISTORY AND DEVELOPMENT

As indicated above, assessment of children's behavior problems requires a multimethod approach in which data are gathered from clinical interviews and self- and other-report sources as well as from direct behavioral observations. In this manner, important information from the cognitive and affective modalities can be obtained and integrated with behavioral data to provide a more complete picture of the child. In addition, the multimethod approach provides the clinician with necessary detail regarding perceptions and reactions of significant others in the child's life (e.g., parents, teachers, peers). It should be noted, however, that this comprehensive and inclusive assessment approach is of relatively recent origin.

In its earliest stages, behavioral assessment of children relied almost exclusively on identification and specification of discrete and highly observable target behaviors (cf. Ullmann & Krasner, 1965). As such, assessment was limited to gathering information solely from the motoric (i.e., behavioral) response modality. This early assessment approach followed logically from theoretical assumptions of the operant school of thought which was in vogue at the time. Early on, behaviorally oriented clinicians posited that the only appropriate behavioral domain for empirical study was that which was directly observable (Skinner, 1953). Contending that objective demonstration of behavior change following intervention was of utmost importance, behaviorists relied upon data that could be measured objectively. Subjectivity, and the inferential process associated with it, were eschewed. Hence the frequency, intensity, and duration of problematic behaviors (i.e., "hard core" measures) were pursued. Although existence of cognitions and affective states was not denied, they were not deemed appropriate subject matter for experimental analysis.

As behavioral treatment approaches with children were broadened to include cognitive and self-control techniques in the 1970s (e.g., Bandura, 1977; Kanfer & Phillips, 1970; Kendall & Hollon, 1980; Meichenbaum, 1977), it became apparent that assessment strategies would have to expand into the cognitive and affective domains as well. Furthermore, even though operant techniques were shown to be efficacious in producing behavior change under controlled conditions, the clinical significance of these changes was less evident. The issue of clinical significance of behavior change is especially important in child behavioral assessment because children are invariably referred for treatment by others (e.g., parents, teachers). Once treatment goals have been identified, the ultimate index of treatment efficacy lies in the referral source's perceptions of change. Hence, other-report measures become as important as direct observational ones.

Furthermore, the scope of behavioral assessment has been expanded to include the impact of large-scale social systems (e.g., schools, neighborhoods) on the child's behavior (e.g., Patterson, 1976; Wahler, 1976). Although inclusion of these additional factors serves to complicate the assessment process, they are an indispensable part of modern-day child behavioral assessment. The ideologies and expectations of seemingly distal social systems often have immediate and profound effects on individual behavior (see Winett, Riley, King, & Altman, 1989, for discussion of these issues).

In sum, child behavioral assessment has progressed from sole reliance on measurement of target behaviors to a broader approach that takes into account cognitive and affective processes of the child that serve to mediate behavior change. Further, the social contexts (i.e., families, schools, communities) in which the problematic behaviors occur have been targeted for change. The assessment techniques that accompany this approach include behavioral interviews and self- and other-report instruments. These measures are utilized in addition to direct behavioral observation which remains the cornerstone of behavioral assessment (Mash & Terdal, 1981, 1989; Ollendick & Hersen, 1984, 1993).

4.06.3 THEORETICAL UNDERPINNINGS

Although behaviorism has had an historical development of its own, it is safe to state that the increased popularity of the behavioral approach has flourished, at least in part, due to dissatisfaction with the psychodynamic approach. A reflection of this dissatisfaction is that virtually all discussions of behavioral assessment are carried out through comparison and contrast with traditional assessment approaches (e.g., Bornstein, Bornstein, & Dawson, 1984; Cone & Hawkins, 1977; Goldfried & Kent, 1972; Hayes, Nelson, & Jarrett, 1986; Mash & Terdal, 1981, 1989; Mischel, 1968; Ollendick & Hersen, 1984, 1993). Though such comparisons often result in oversimplification of both approaches, they serve to elucidate theoretical underpinnings of the behavioral approach and its unique contributions. In this section, we will contrast the theoretical assumptions that guide behavioral and traditional assessment and discuss the practical implications of these assumptions for child behavioral assessment.

The most fundamental difference between traditional and behavioral assessment lies in the conception of "personality" and behavior (we place the construct "personality" in quotations because early behaviorists would have objected to use of this term, given its subjectivity and imprecise meaning). In the traditional assessment approach, personality is viewed as a reflection of underlying and enduring traits, and behavior is assumed to be caused by these internal personality characteristics ("personalism"). Aggressive behavior, for example, is assumed to reside "in" the child and to be caused by an underlying dynamic process attributed, perhaps, to hostility or anger and resulting from deep-seated intrapsychic conflict. "Aggression," it is said, is caused by the underlying hostility/anger. In contrast, behavioral approaches have avoided references to underlying personality constructs, focusing instead on what the child does under specific conditions. From the behavioral perspective, "personality" refers to patterns rather than causes of behavior (Staats, 1975, 1986). Furthermore, behavior is viewed as a result of current environmental factors ("situationalism") and of current environmental factors interacting with organismic variables ("interactionism"). Thus the role of the current environment is stressed more in behavioral assessment than in traditional assessment. The focus of assessment is on what the child does in that situation rather than on what the child has or "is" (Mischel, 1968). As a result, a lower level of inference is required in behavioral assessment than in traditional assessment.

It is important not to oversimplify the behavioral view of the causes of behavior, however. It has often been erroneously asserted that the behavioral approach focuses on external determinants of behavior to the exclusion of organismic states or internal cognitions and affects. To be sure, behavioral views of childhood disorders have emphasized the significant role of environmental factors in the manifestation and maintenance of behavior. However, organismic variables that influence behavior are not ignored or discounted. Among the organismic variables—dubbed cognitive social learning person variables (CSLPVs) by Mischel (1973)—that have been found to be important are competencies (skills which children possess such as social skills, problem-solving skills), encoding strategies (the manner in which children perceive or encode information about their environment), expectancies (expectancies about performance, including self-efficacy and outcome expectancies), subjective values (children's likes or dislikes, preferences or aversions), and self-regulatory systems and plans (children's capacity for and manner of self-imposing goals and standards and self-administering consequences for their behavior). A wide array of self-report instruments tapping CSLPVs and related cognitive and affective modalities for use in child behavioral assessment have been reviewed recently by us (Greene & Ollendick, in press). A thorough behavioral assessment should attempt to identify controlling variables, whether environmental or organismic in nature. As Mash and Terdal (1981) point out, "the relative importance of organismic and environmental variables and their interaction . . . should follow from a careful analysis of the problem" (p. 23).

The traditional conception of personality as made up of stable and enduring traits implies that behavior will be relatively persistent over time and consistent across situations. The behavioral view, in contrast, has been one of situational specificity; that is, because behavior is in large part a function of situational determinants and CSPLVs that are enacted only under specified conditions, a child's behavior will change as these situational factors are altered or the person variables are engaged. Similarly, consistency of behavior across the temporal dimension is not necessarily expected. Hence, as noted above, an aggressive act such as a child hitting another child would be seen from the traditional viewpoint as a reflection of underlying hostility which, in turn, would be hypothesized to be related to early life experiences or intrapsychic conflict. Little or no attention would be given to specific situational factors or the environmental context in which the aggressive act occurred. From the behavioral perspective, an attempt is made to identify those variables that elicit and maintain the aggressive act in that particular situation. That the child may aggress in a variety of situations is explained in terms of his or her learning history in which reinforcing consequences have been obtained for past aggressive acts (which help shape CSLPVs), and not in terms of an underlying personality trait of hostility. From this analysis, it is clear that actual behavior is of utmost importance to behaviorists, because it represents a sample of the child's behavioral repertoire in a specific situation. From the traditional viewpoint, the behavior assumes importance only insofar as it is a sign of some underlying trait.

These differing assumptions have implications for the assessment process. In behavioral assessment, the emphasis on situational specificity necessitates an assessment approach that samples behavior across a number of settings. Hence assessment of the child's behavior at home, in school, and on the playground is important in addition to information obtained in the clinic setting. Furthermore, it is not assumed that information obtained from these various settings will be consistent. The child may behave aggressively in school and on the playground with peers but not at home with siblings or parents. Or conversely, the child might behave aggressively at home but not at school or when with his or her peers. This lack of consistency in behavior would be problematic for the traditional approach, but not for the behavioral approach. Similarly, the notion of temporal instability requires the child's behavior be assessed at several points in time from a behavioral perspective, whereas such measurements across time would be less critical for the traditional approach.

At one point in time, it was relatively easy to differentiate behavioral from traditional assessment on the basis of the methods employed. Direct behavioral observation was the defining characteristic and often the sole assessment technique of the behavioral approach, whereas clinical interviews, self-report measures, and projective techniques characterized traditional assessment. However, as behavioral assessment was expanded to include a wider repertoire of assessment methods, differentiating behavioral and traditional assessments simply on the basis of assessment methods used has become more difficult. It is not uncommon for behaviorists to utilize information from clinical interviews and self-report instruments, and to pursue perceptions and expectancies of significant others in the child's environment. Thus there is considerable overlap in actual assessment practices, with one notable exception. Rarely, if ever, would projective techniques be utilized by the child behavioral assessor. The primary difference between traditional and behavioral assessment lies then not in the methods employed, but rather in the manner in which data from assessment sources are utilized. Traditional approaches interpret assessment data as signs of underlying personality functioning. These data are used to diagnose and classify the child and to make prognostic statements. From the behavioral perspective, assessment data are used to identify target behaviors and their controlling conditions (again, be they overt or covert). Information obtained from assessment serves as a sample of the child's behavior under specific circumstances. This information guides the selection of appropriate treatment procedures. Because behavioral assessment is ongoing, such information serves as an index by which to evaluate critically the effects of treatment and to make appropriate revisions in treatment. Further, because assessment data are viewed as samples of behavior, the level of inference is low, whereas a high level of inference is required when one attempts to make statements about personality functioning from responses to interview questions or test items.

In addition to these differences, Cone (1986) has highlighted the nomothetic and ideographic distinction between traditional and behavioral assessment. Stated briefly, the nomothetic approach is concerned with the discovery of general laws as they are applied to large numbers of children. Usually, these laws provide heuristic guidelines as to how certain variables are related to one another. Such an approach can be said to be variable-centered because it deals with particular characteristics (traits) such as intelligence, achievement, assertion, aggression, and so on. In contrast, the ideographic approach is concerned more with the uniqueness of a given child and is said to be child-centered rather than variable-centered. Unlike the nomothetic approach, the ideographic perspective emphasizes discovery of relationships among variables uniquely patterned in each child. The ideographic approach is most akin to the behavioral perspective, whereas the nomothetic approach is closely related to the traditional approach. As Mischel (1968) observed, "Behavioral assessment involves an exploration of the unique or idiosyncratic aspects of the single case, perhaps to a greater extent than any other approach" (p. 190). Cone (1986) illustrates how the ideographic/nomothetic distinction relates to the general activities of behavioral assessors by exploring five basic questions: What is the purpose of assessment? What is its specific subject matter? What general scientific approach guides this effort? How are differences accounted for? And, to what extent are currently operative environmental variables considered? Although further discussion of these important issues is beyond the scope of the present chapter, Cone's schema helps us recognize the pluralistic nature of behavioral assessment and calls our attention to meaningful differences in the practices contained therein. As Cone (1986) concludes, "There is not one behavioral assessment, there are many" (p. 126). We agree.

In sum, traditional and behavioral assessment approaches operate under different assumptions regarding the child's behavior. These assumptions, in turn, have implications for the assessment process. Of paramount importance for child behavior assessors is the necessity of tailoring the assessment approach to the specific difficulties of the child in order to identify the problem accurately, specify treatment, and evaluate treatment outcome. Such tailoring requires ongoing assessment from a number of sources under appropriately diverse stimulus conditions.

4.06.4 DESCRIPTION OF ASSESSMENT PROCEDURES

Multimethod behavioral assessment of children entails use of a wide variety of specific procedures. As behavioral approaches with children evolved from sole reliance on operant procedures to those involving cognitive and self-control procedures, the methods of assessment have changed accordingly. Identification of discrete target behaviors has been expanded to include assessment of cognitions and affects, as well as large-scale social systems that affect the child (e.g., families, schools, communities).

Information regarding these additional areas can be obtained most efficiently through behavioral interviews, self-reports, and other-reports. Cone (1978) has described these assessment methods as indirect ones; that is, while they may be used to measure behaviors of clinical relevance, they are obtained at a time and place different from when the behaviors actually occurred. In both behavioral interviews and self-report questionnaires, a verbal representation of the behaviors of interest is obtained. Other-reports, or ratings by others such as parents or teachers, are also included in the indirect category because they involve retrospective descriptions of behavior. Generally, a significant person in the child's environment (e.g., at home or school) is asked to rate the child based on previous observations in that setting (recollections).

As noted by Cone (1978), ratings such as these should not be confused with direct observation methods, which assess behaviors of interest at the time and place of their occurrence. Of course, information regarding cognition and affects, as well as the situations or settings in which they occur, can also be obtained through direct behavioral observations, either by self-monitoring or through trained observers. In the sections that follow, both indirect and direct methods are reviewed.

4.06.4.1 Behavioral Interviews

The first method of indirect assessment to be considered is the behavioral interview. Of the many procedures employed by behavioral clinicians, the interview is the most widely used (Swann & MacDonald, 1978) and is generally considered an indispensable part of assessment (Gross, 1984; Linehan, 1977). Behavioral interviews are frequently structured to obtain information about the target behaviors and their controlling variables and to begin the formulation of specific treatment plans. While the primary purpose of the behavioral interview is to obtain information, we have found that traditional "helping" skills including reflections, clarifications, and summary statements help put children and their families at ease and greatly facilitate collection of this information (Ollendick & Cerny, 1981). As with traditional therapies, it is important to establish rapport with the child and family and to develop a therapeutic alliance (i.e., agreement on the goals and procedures of therapy) in the assessment phase of treatment (Ollendick & Ollendick, 1997).

Undoubtedly, the popularity of the behavioral interview is derived in part from practical considerations associated with its use. While direct observation of target behaviors remains the hallmark of behavioral assessment, such observations are not always practical or feasible. At times, especially in outpatient therapy in clinical settings, the clinician might have to rely on children's self-report as well as that of their parents to obtain critical detail about problem behaviors and their controlling variables. Further, the interview affords the clinician the opportunity to obtain information regarding overall functioning in a number of global areas (e.g., home, school, neighborhood), in addition to specific information about particular problem areas. The flexibility inherent in the interview also allows the clinician to build a relationship with the child and the family and to obtain information that might otherwise not be revealed. As noted early on by Linehan (1977), some family members may be more likely to divulge information verbally in the context of a professional relationship than to write it down on a form to be entered into a permanent file. In our experience, this is not an uncommon occurrence. That is, certain family members report little or no difficulties on intake reports or on self-report measures, yet they divulge a number of problem areas during the structured behavioral interview.

In addition, the interview allows the clinician the opportunity to observe the family as a whole and to obtain information about the familial context in which the problem behaviors occur. Several interrelated issues may arise when child behavioral assessment is expanded to include the family unit (Evans & Nelson, 1977; Ollendick & Cerny, 1981). First, children rarely refer themselves for treatment; invariably, they are referred by adults whose perceptions of problems may not coincide with the child's view. This is especially true when problems are centered around externalizing behaviors such as oppositional or disruptive behaviors, less so with internalizing behaviors (e.g., anxiety or depression). Moreover, it is not uncommon for the perception of one adult to differ from that of another (i.e., the mother and father disagree, or the teacher and the parents disagree; cf, Achenbach, McConaughy, & Howell, 1987). A second issue, related to the first, is the determination of when child behaviors are problematic and when they are not. Normative developmental comparisons are useful in this regard (Lease & Ollendick, 1993; Ollendick & King, 1991). It is not uncommon for parents to refer 3-year-olds who wet the bed, 5-year-olds who reverse letters, 10-year-olds who express interest in sex, and 13-year-olds who are concerned about their physical appearance. Frequently, these referrals are based on parental uneasiness or unrealistic expectations rather than genuine problems (see Campbell, 1989, for further discussion of these issues). Finally, problematic family interactions (especially parent–child interactions) are frequently observed in families in which a particular child has been identified and referred for treatment (cf. Dadds, Rapee, & Barrett, 1994; Patterson, 1976, 1982). These interactions may not be a part of the parents' original perception of the "problem." Furthermore, assessment of such interactions allows the clinician an opportunity to observe the verbal and nonverbal behaviors of the family unit in response to a variety of topics, and of family members in response to each other. Structured interviews assessing parent–child interactions have been developed for a number of behavior problems (e.g., Barkley, 1987; Dadds et al., 1994).

Ideally, evaluation of parental perceptions and parent–child interactions will enable the clinician to conceptualize the problematic behaviors and formulate treatment plans from a more comprehensive, integrated perspective. However, the above discussion is not meant to imply that the behavioral interview should be limited to the family; in many instances, the practices described above should be extended to adults outside the family unit, such as teachers, principals, and physicians, and to environments beyond the home, including schools and daycare centers. For example, if a problem behavior is reported to occur primarily at school, assessing the perceptions and behavioral goals of a teacher and/or principal will be necessary (Greene, 1995, 1996), and evaluating teacher–

student interactions may prove more productive than observing parent–child interactions during the clinical interview. Finally, the clinician should approach the behavioral interview with caution and avoid blind acceptance of the premise that a "problem" exists "in" the child. Information obtained in a comprehensive assessment may reveal the behavior of the identified client is only a component of a more complex clinical picture involving parents, siblings, other adults, and/or social systems.

In sum, an attempt is made during the behavioral interview to obtain as much information as possible about the child, his or her family, and other important individuals and environments. While the interview is focused around specific target behaviors, adult–child interactions and adult perceptions of the problem may also be assessed. These perceptions should be considered tentative, however, and used primarily to formulate hypotheses about target behaviors and their controlling variables and to select additional assessment methods to explore target behaviors in more depth (e.g., rating scales, self-reports, self-monitoring, and behavioral observations). The behavioral interview is only the first step in the assessment process.

Brief mention should also be made here of structured diagnostic interviews and their role in child behavioral assessment. In some instances, most notably when a diagnosis is required, it may be desirable for the clinician to conduct a structured diagnostic interview. In general, diagnostic interviews are oriented toward obtaining specific information to determine if a child "meets" diagnostic criteria for one or more specific diagnoses included in the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*) (American Psychiatric Association, 1994) or the *International classification of diseases* (10th ed., *ICD-10*; World Health Organization, 1991). Such interviews facilitate collection of data relative to a broad range of "symptoms" (i.e., behaviors) and psychiatric diagnoses. Several "omnibus" diagnostic interviews are available, including the Diagnostic Interview Schedule for Children-Version 2.3 (Shaffer, 1992), which was recently revised to reflect *DSM-IV* criteria. Other diagnostic interviews are oriented toward a specific domain such as anxiety (e.g., the Anxiety Disorders Interview Schedule for Children; Silverman & Nelles, 1988). It, too, has recently been revised to incorporate *DSM-IV* criteria (Silverman & Albano, 1996). Both child and parent forms of these interviews are available. Although these structured diagnostic interviews provide a wealth of information, they are limited by an overemphasis on diagnostic categories (to the exclusion of important details regarding specific target behaviors and their controlling variables), weak or untested reliability for children under age 11, low correspondence between responses of children and their parents, and categorical vs. dimensional scoring criteria (McConaughy, 1996). Further, structured diagnostic interviews often do not yield specific information about contextual factors associated with the child's problematic behavior; thus, when a diagnostic interview is used, it needs to be supplemented with a problem-focused interview. In our opinion, diagnostic interviews should not be considered as replacements for problem-focused interviews; rather they should be viewed as complementary.

4.06.4.2 Ratings and Checklists

Following the initial behavioral interview and, if necessary, the diagnostic interview, significant others in the child's environment may be requested to complete rating forms or checklists. In general, these forms are useful in providing an overall description of the child's behavior, in specifying dimensions or response clusters that characterize the child's behavior, and in serving as outcome measures for the evaluation of treatment efficacy. Many of these forms contain items related to broad areas of functioning such as school achievement, peer relationships, activity level, and self-control. As such, they provide a cost-effective picture of children and their overall level of functioning. Further, the forms are useful in eliciting information that may have been missed in the behavioral interview (Novick, Rosenfeld, Bloch, & Dawson 1966). Finally, the forms might prove useful in the search for the best match between various treatments (e.g., systematic desensitization, cognitive restructuring, and self-control) and subtypes of children as revealed on these forms (Ciminero & Drabman, 1977).

The popularity of omnibus rating forms and checklists is evident in the number of forms currently available (McMahon, 1984). Three of the more frequently used forms are described here: the Behavior Problem Checklist (Quay & Peterson, 1967, 1975) and its revision (Quay & Peterson, 1983); the Child Behavior Checklist (Achenbach, 1991a, 1991b); and the recently developed Behavior Assessment System for Children (Reynolds & Kamphaus, 1932). Based on Peterson's (1961) early efforts to sample diverse child behavior problems, the Revised Behavior Problem Checklist consists of 89 items, each rated on a three-point severity scale. While some of the items are general and require considerable inference (e.g., lacks self-confidence, jealous), others are more specific (e.g., cries, sucks thumb). Six primary dimensions or response clusters of child behavior have been identified on this scale: conduct problems, socialized aggression, attention problems, anxiety-withdrawal, psychotic behavior, and motor excess. Interestingly, the two primary problem clusters found on this checklist are similar to those found in numerous factor-analytic studies of other rating forms and checklists. These two factors or response clusters represent consistent dimensions of child behavior problems, reflecting externalizing (e.g., acting out) and internalizing (e.g., anxiety, withdrawal) dimensions of behavior (Achenbach, 1966).

While the Behavior Problem Checklist has a rather lengthy history and is one of the most researched scales, it does not include the rating of positive behaviors and, hence, does not provide a basis on which to evaluate more appropriate, adaptive behaviors. A scale that does assess appropriate behaviors, as well as inappropriate ones, is the Child Behavior Checklist (CBCL; Achenbach, 1991a, 1991b; Achenbach & Edelbrock, 1989). The scale, designed for both parents and teachers, contains both social competency and behavior problem items. The parent-completed CBCL is available in two formats depending on the age of the child being evaluated (i.e., 2–3 years and 4–18 years). The CBCL 4–18, for example, consists of 112 items rated on a three-point scale. Scored items can be clustered into three factor-analyzed profiles: social competence, adaptive functioning, and syndrome scales. The latter includes eight syndrome scales: withdrawn, somatic complaints, anxious/depressed, social problems, thought problems, attention problems, aggressive behavior, and delinquent behavior. Social competency items examine the child's participation in various activities (e.g., sports, chores, hobbies) and social organizations (e.g., clubs, groups), as well as performance in the school setting (e.g., grades, placements, promotions). The teacher-completed CBCL (TRF; Teacher Report Form) also consists of 112 items which are fairly similar, but not completely identical to, those found on the CBCL completed by parents. The scored items from the teacher form cluster into the same three factor-analyzed profiles; further, the eight syndrome scales are the same for the two measures, allowing for cross-informant comparisons. As with Quay and Peterson's Behavior Problem Checklist, some of the items are general and require considerable inference (e.g., feels worthless, acts too young, fears own impulses), while others are more specific and easily scored (e.g., wets bed, sets fires, destroys own things). Broadband grouping of the factors reflects the aforementioned internalizing and externalizing behavioral dimensions.

Although the Behavior Problem Checklist and Child Behavior Checklist have enjoyed considerable success, the recently developed Behavior Assessment System for Children (BASC; Reynolds & Kamphaus, 1992) represents a challenge to both of these well-established rating scales. Like these other instruments, the BASC is an omnibus checklist composed of parent, teacher, and child versions. It also contains a developmental history form and a classroom observation form. Most similar to Achenbach's Child Behavior Checklist (Achenbach, 1991a), Teacher's Report Form (Achenbach, 1991b), and Youth Self-Report (Achenbach, 1991c), the parent, teacher, and self-report forms of the BASC contain items that tap multiple emotional and behavioral domains and produce scale scores that represent pathological and adaptive characteristics of the child. Unlike the empirically derived scales of Achenbach's checklists, however, the scales of the BASC were created conceptually to represent content areas relevant to assessment and classification in clinical and educational settings.

For example, the BASC Parent Rating Scale (BASC-PRS) yields *T* scores in broad externalizing and internalizing domains as well as in specific content areas, including aggression, hyperactivity, conduct problems, attention problems, depression, anxiety, withdrawal, somatization, and social skills.

In addition, it provides *T* scores in areas of social competency such as leadership and adaptability. Preschool (ages 4–5), child (ages 6–11), and adolescent (ages 12–18) forms are available. Recent findings suggest the utility of this instrument with both clinical and educational populations and in identifying youth at risk for maladaptive outcomes (cf, Doyle, Ostrander, Skare, Crosby, & August, 1997). Although initial findings associated with its use appear promising, much more research is needed before its routine acceptance can be endorsed.

In addition to these more general rating forms, rating forms specific to select problem areas are also available for use in child behavioral assessment. Three such forms have been chosen for purposes of illustration: one used in the assessment of an internalizing dimension (fears/anxiety), another in the assessment of an externalizing dimension (defiance/noncompliance), and the final one in measuring a specific area of social competency.

The Louisville Fear Survey Schedule for Children (Miller, Barrett, Hampe, & Noble,

1972) contains 81 items that address an extensive array of fears and anxieties found in children and adolescents. Each item is rated on a three-point scale by the child's parents. Responses to specific fear items can be used to subtype fearful children. For example, Miller et al. (1972) were able to differentiate among various subtypes of school-phobic children on the basis of this instrument.

The Home Situations Questionnaire (HSQ; Barkley, 1981; Barkley & Edelbrock, 1987) contains 16 items representing home situations in which noncompliant behavior may occur (e.g., while playing with other children, when asked to do chores, and when asked to do homework). For each situation, parents indicate whether noncompliant behavior is a problem and then rate each of the 16 problematic situations on a nine-point scale (mild to severe); thus the scale assesses both the number of problem situations and the severity of noncompliant behavior. The HSQ has been shown to be sensitive to stimulant-drug effects (Barkley, Karlsson, Strzelecki, & Murphy, 1984), to discriminate children with behavior problems from normal children (Barkley, 1981), and to be sensitive to the effects of parent training programs (Pollard, Ward, & Barkley, 1983). The HSQ was selected for inclusion in this chapter because it may also be used in conjunction with a companion scale, the School Situations Questionnaire (SSQ; Barkley, 1981; Barkley & Edelbrock, 1987), which is completed by teachers. This scale includes 12 school situations most likely to be problematic for clinic-referred, noncompliant children, including "during lectures to the class," "at lunch," and "on the bus." Teachers rate the occurrence and severity of noncompliant behavior on a scale identical to that of the HSQ. In earlier sections, we emphasized the importance of assessing child behavior in multiple environments; the HSQ and SSQ are representative of recent efforts to develop measures for this purpose, thus providing us important contextual information about specific problem behaviors.

In some instances, it may be useful to obtain more information about a positive, adaptive domain of behavior—such as social skills or self-regulation—than that provided for by omnibus rating scales such as the Revised Behavior Problem Checklist (Quay & Peterson, 1983) or the Child Behavior Checklist (Achenbach, 1991a, 1991b). For example, the Social Skills Rating System (Gresham & Elliot, 1990), a 55-item questionnaire, provides specific information about a child's behavior in three domains (social skills, problem behaviors, and academic competence). Parent, teacher, and self-rating forms are available. In general, this instrument provides important and detailed information about academic and social competence that can be used to supplement information obtained from the more generic rating scales.

In sum, a variety of other-report instruments are available. As noted earlier, these forms must be considered indirect methods of assessment because they rely on retrospective descriptions of the child's behavior. For all of these scales, an informant is asked to rate the child based on past observations of that child's behavior. Global scales such as the Revised Behavior Problem Checklist, Child Behavior Checklist, and Behavior Assessment Scale for Children comprehensively sample the range of potential behavior problems, while more specific scales such as the Louisville Fear Survey Schedule for Children, the Home Situations Questionnaire, and the Social Skills Rating System provide detailed information about particular maladaptive or adaptive behaviors. Both types of other-report instruments provide useful, albeit different, information in the formulation and evaluation of treatment programs.

4.06.4.3 Self-report Instruments

Concurrent with the collection of other-reports regarding the child's behavior from significant others, self-reports of attitudes, feelings, and behaviors may be obtained directly from the child. As noted earlier, behaviorists initially eschewed such data, maintaining that the only acceptable datum was observable behavior. To a large extent, this negative bias against self-report was an outgrowth of early findings indicating that reports of subjective states did not always coincide with observable behaviors (Finch & Rogers, 1984). While congruence in responding is, in fact, not always observed, contemporary researchers have cogently argued that children's perceptions of their own behavior and its consequences may be as important for behavior change as the behavior itself (Finch, Nelson, & Moss, 1993; Ollendick & Hersen, 1984, 1993). Furthermore, as noted earlier, although different assessment procedures may yield slightly different information, data from these sources should be compared and contrasted in order to produce the best picture of the child and to derive treatment goals and procedures. Although self-report instruments have specific limitations, they can provide valuable information about children and their presenting problem; furthermore, they can be used as an index of change following treatment.

A wide array of self-report instruments have been developed for children. Some self-report instruments focus on a broad range of behavioral, cognitive, and affective functioning, as in the case of the Youth Self-report (Achenbach, 1991c). Other self-report instruments tap more specific areas of interest, such as anger (Nelson & Finch, 1978), anxiety (Reynolds & Richmond, 1985; Spielberger, 1973), assertion (Deluty, 1979; Ollendick, 1983a), depression (Kovacs, 1985), and fear (Scherer & Nakamura, 1968). Each of these instruments has been carefully developed and empirically validated. Three of the more frequently used instruments we have found to be useful in our clinical practice will be described briefly.

Spielberger's State–Trait Anxiety Inventory for Children (1973) consists of 20 items that measure state anxiety and 20 items that tap trait anxiety. The state form is used to assess transient aspects of anxiety, while the trait form is used to measure more global, generalized aspects of anxiety. Combined, the two scales can provide both process and outcome indices of change in self-reported anxiety. That is, the state form can be used to determine session-by-session changes in anxiety, while the trait form can be used as a pretreatment, posttreatment, and follow-up measure of generalized anxiety. A clear advantage of this instrument is that the state scale is designed so responses to relatively specific anxiety-producing situations can be determined. For example, children can be instructed to indicate how they feel "at this moment" about standing up in front of class, leaving home for summer camp, or being ridiculed by peers. Further, cognitive, motoric, and physiologic indicators of anxiety can be endorsed by the child (e.g., feeling upset, scared, mixed up, jittery, or nervous). Responses to items are scored on a three-point scale (e.g., "I feel very scared/scared/not scared"). Finally, the pervasiveness of the anxiety response can be measured by the trait form. The Spielberger scales are most useful for children aged 9–12, but have been used with both younger children and adolescents as well.

A second instrument that has been used frequently in child behavioral assessment is the Fear Survey Schedule for Children (Scherer & Nakamura, 1968) and its revision (Ollendick, 1983b). In the revised scale, designed to be used with younger and middle-age (9–12) children, children are instructed to rate their level of fear to each of 80 items on a three-point scale. They are asked to indicate whether a specific fear item (e.g., having to go to school, snakes, dark places, riding in a car) frightens them "not at all," "some," or "a lot." Factor analysis of the scale has revealed five primary factors: fear of failure or criticism, fear of the unknown, fear of injury and small animals, fear of danger and death, and medical fears. This pattern of fear has been shown to be relatively invariant across several nationalities, including American (Ollendick, Matson & Hetsel, 1985), Australian (Ollendick, King, & Frary, 1989), British (Ollendick, Yule, & Ollier, 1991), Chinese (Dong, Yang, & Ollendick, 1994), and Nigerian youth (Ollendick, Yang, King, Dong, & Akande, 1996). Further, it has been shown that girls report more fear than boys in these various countries, that specific fears change developmentally, and that the most prevalent fears of boys and girls have remained unchanged over the past 30 years (although some differences have been noted across nationalities). Such information is highly useful when determining whether a child of a specific age and gender is excessively fearful. Further, the instrument has been used to differentiate subtypes of phobic youngsters whose fear of school is related to separation anxiety (e.g., death, having parents argue, being alone) from those whose fear is due to specific aspects of the school situation itself (e.g., taking a test, making a mistake, being sent to the principal). When information from this instrument is combined with that from parents on the Louisville Fear Survey Schedule for Children (Miller et al., 1972), a relatively complete picture of the child's characteristic fear pattern can be obtained.

The final self-report instrument to be reviewed is Kovac's (1985) Children's Depression Inventory (CDI). Since the mid-1980s, no other area in clinical child psychology has received more attention than depression in children. A multitude of issues regarding its existence, nature, assessment, and treatment have been examined (Cantwell, 1983; Rutter, 1986). One of the major obstacles to systematic investigations in this area has been the absence of an acceptable self-report instrument, and the CDI appears to meet this need. The instrument is a 27-item severity measure of depression based on the well-known Beck Depression Inventory. Each of the 27 items consists of three response choices designed to range from mild depression to fairly severe and clinically significant depression. Kovacs reports that the instrument is suitable for middle-age children and adolescents (8–17 years of age). We have found the instrument to be useful with younger children as well, especially when items are read aloud and response choices are depicted on a bar graph. Smucker, Craighead, Craighead, and Green (1986) have provided additional psychometric data on the CDI. Overall, they conclude it is a reliable, valid, and clinically useful instrument for children and adolescents.

In sum, a variety of self-report instruments are available. As with other-report forms, self-reports should be used with appropriate caution and due regard for their specific limitations. Because they generally involve the child's retrospective rating of attitudes, feelings, and behaviors, they too must be considered indirect methods of assessment (Cone, 1978). Nevertheless, they can provide valuable information regarding children's own perception of their behavior.

4.06.4.4 Self-monitoring

Self-monitoring differs from self-report in that it constitutes an observation of clinically relevant target behaviors (e.g., thoughts, feelings, actions) at the time of their occurrence (Cone, 1978). As such, it is a direct method of assessment. Self-monitoring requires children to observe their own behavior and then to record its occurrence systematically. Typically, the child is asked to keep a diary, place marks on a card, or push the plunger on a counter as the behavior occurs or shortly thereafter. Although self-monitoring procedures have been used with both children and adults, at least three considerations must be attended to when such procedures are used with younger children (Shapiro, 1984): behaviors should be clearly defined, prompts to use the procedures should be readily available, and rewards for their use should be provided. Some younger children will be less aware of when the target behavior is occurring and will require coaching and assistance prior to establishing a monitoring system. Other young children may have difficulty remembering exactly what behaviors to monitor and how those behaviors are defined. For these reasons, it is generally considered advisable to provide the child with a brief description of the target behavior or, better yet, a picture of it, and to have the child record only one or two behaviors at a time. In an exceptionally sensitive application of these guidelines, Kunzelman (1970) recommended the use of COUNTOONS, simple stick figure drawings that depict specific behaviors to be self-monitored. Children are instructed to place a tally mark next to the picture when the behavior occurs. For example, a girl monitoring hitting her younger brother may be given an index card with a drawing of a girl hitting a younger boy and instructed to mark each time she does what the girl in the picture is doing. Of course, in a well-designed program, the girl might also be provided with a picture of a girl and a younger boy sharing toys and asked as well to mark each time she emits the appropriate behavior. Such pictorial cues serve as visual prompts for self-monitoring. Finally, children should be reinforced profusely following successful use of self-monitoring.

In general, methods of self-monitoring are highly variable and depend on the specific behavior being monitored and its place of occurrence. For example, Shapiro, McGonigle, and Ollendick (1980) had mentally retarded and emotionally disturbed children self-monitor on-task behavior in a school setting by placing gummed stars on assignment sheets; Ollendick (1981) had children with tic disorders place tally marks upon the occurrence of tics on a colored index card carried in the child's pocket; and Ollendick (1995) had adolescents diagnosed with panic disorder and agoraphobia indicate the extent of their agoraphobic avoidance on a 1–5 scale each time they encountered the feared situation. He also had the adolescents indicate their confidence (i.e., self-efficacy) in coping with their fear on a similar 1–5 scale. In our clinical work, we have also used wrist counters with children whose targeted behaviors occur while they are "on the move." Such a device is not only easy to use, but serves as a visual prompt to self-record. The key to successful self-monitoring in children is the use of recording procedures that are uncomplicated. They must be highly portable, simple, time-efficient, and relatively unobtrusive (Greene & Ollendick, in press).

In sum, self-monitoring procedures represent a direct means of obtaining information about the target behaviors as well as their antecedents and consequences. While specific monitoring methods may vary, any procedure that allows the child to monitor and record presence of the targeted behaviors can be used. When appropriate procedures are used, self-monitoring represents a direct and elegant method of assessment (Ollendick & Greene, 1990; Ollendick & Hersen, 1993).

4.06.4.5 Behavioral Observation

Direct observation of the child's behavior in the natural environment is the hallmark of child behavioral assessment. As described by Johnson and Bolstad (1973), the development of naturalistic observation procedures represents one of the major, if not the major, contributions of the behavioral approach to assessment and treatment of children. A direct sample of the child's behavior at the time and place of its occurrence is obtained with this approach. As such, it is the least inferential of the assessment methods described heretofore. However, behavioral observations in the naturalistic environment should not be viewed as better than other methods of assessment. Rather, direct observations should be viewed as complementary to the other methods, with each providing different and valuable information.

In behavioral observation systems, a single behavior or set of behaviors that have been identified as problematic (generally through the aforementioned procedures) are operationally defined, observed, and recorded in a systematic fashion. In addition, events that precede and follow behaviors of interest are recorded and subsequently used in development of specific treatment programs. Although Jones, Reid, and Patterson (1975) have recommended use of "trained impartial observer-coders" for collection of these data, this is rarely possible in the practice of child behavioral assessment in the clinical setting. Frequently, time constraints, lack of trained personnel, and insufficient resources mitigate against the use of highly trained and impartial observers. In some cases, we have used significant others in the child's environment (e.g., parents, teachers, siblings) or the children themselves as observers of their own behavior. Although not impartial, these observers can be trained adequately to record behaviors in the natural environment. In other cases, behavioral clinicians have resorted to laboratory or analogue settings that are similar to, but not identical to, the natural environment. In these simulated settings, children may be asked to behave as if they are angry with their parents, to role play assertive responding, or to approach a highly feared object. Behaviors can be directly observed or videotaped (or audiotaped) and reviewed retrospectively. The distinguishing characteristic of behavioral observations, whether made in the naturalistic environment or in simulated settings, is that a direct sample of the child's behavior is obtained.

A wide variety of target behaviors have been examined using behavioral observation procedures. These behaviors have varied from relatively discrete behaviors like enuresis and tics, that require relatively simple and straightforward recording procedures, to complex social interactions that necessitate extensive behavioral coding systems (e.g., Dadds et al., 1994; O'Leary, Romanczyk, Kass, Dietz, & Santogrossi, 1971; Patterson, Ray, Shaw, & Cobb, 1969; Wahler, House, & Stambaugh, 1976).

The utility of behavioral observations in naturalistic and simulated settings is well illustrated in Aylion, Smith, and Rogers' (1970) behavioral assessment of a young school-phobic girl. In this case study, impartial observers in the child's home monitored the stream of events occurring on school days in order to identify the actual school-phobic behaviors and to determine the antecedent and consequent events associated with them. In this single-parent family, it was noted that the mother routinely left for work about one hour after the targeted girl (Valerie) and her siblings were to leave for school. Although the siblings left for school without incident, Valerie was observed clinging to her mother and refusing to leave the house and go to school. As described by Ayllon et al. (1970), "Valerie typically followed her mother around the house, from room to room, spending approximately 80 percent of her time within 10 feet of her mother. During these times there was little or no conversation" (p. 128). Given her refusal to go to school, the mother took Valerie to a neighbor's apartment for the day. However, when the mother attempted to leave for work, Valerie frequently followed her at a 10-foot distance. As a result, the mother had to return to the neighbor's apartment with Valerie in hand. This daily pattern was observed to end with the mother "literally running to get out of sight of Valerie" so she would not follow her to work. During the remainder of the day, it was observed that Valerie was allowed to do whatever she pleased: "Her day was one which would be considered ideal by many grade-school children—she could be outdoors and play as she chose all day long. No demands of any type were placed on her" (p. 129). Based on these observations, it appeared that Valerie's separation anxiety and refusal to attend school were related to her mother's attention and to the reinforcing environment of the neighbor's apartment where she could play all day.

However, because Valerie was also reported to be afraid of school itself, Ayllon et al. (1970) designed a simulated school setting in the home to determine the extent of anxiety or fear toward specific school-related tasks. (Obviously, observation in the school itself would have been desirable but was impossible because she refused to attend school.) Unexpected, little or no fear was evinced in the simulated setting; in fact, Valerie performed well and appeared to enjoy the school-related setting and homework tasks. In this case, these detailed behavioral observations were useful in ruling upon differential hypotheses related to school refusal. They led directly to a specific and efficacious treatment program based on shaping and differential reinforcement principles. The utility of behavioral observations for accurate assessment and treatment programming has been noted in numerous other case studies as well (e.g., Ollendick, 1995; Ollendick & Gruen, 1972; Smith & Sharpe, 1970).

A major disadvantage of behavioral observations in the natural environment is that the target behavior may not occur during the designated observation periods. In such instances, simulated settings that occasion the target behaviors can be used. Simulated observations are especially helpful when the target behavior is of low frequency, when the target behavior is not observed in the naturalistic setting due to reactivity effects associated with being observed, or when the target behavior is difficult to observe in the natural environment due to practical constraints. Ayllon et al.'s (1970) use of a simulated school setting illustrated this approach under the latter conditions. A study by Matson and Ollendick (1976) illustrates this approach for low-frequency behaviors. In this study, parents reported that their children bit either the parent or siblings when they "were unable to get their way or were frustrated." Direct behavioral observations in the home confirmed the parental report, but it was necessary to observe the children for several hours prior to observing an occurrence of the behavior. Further, parents reported that their children were being "good" while the observers were present and that frequency of biting was much lower than its usual, "normal" rate. Accordingly, parents were trained in observation procedures and instructed to engage their children in play for four structured play sessions per day. During these sessions, parents were instructed to prompt biting behavior by deliberately removing a preferred toy. As expected, removal of favored toys in the structured situations resulted in increases in target behaviors, which were then eliminated through behavioral procedures. The structured, simulated play settings maximized the probability that biting would occur and that it could be observed and treated under controlled conditions.

It is often intimated that behavioral observation systems may not be suitable for more complex behavior problems, such as parent–child interactions. Sophisticated systems developed by Dumas (1989) and Dadds et al. (1994) to capture family interactions and processes suggest otherwise. For example, Dadds et al. (1994) developed the Family Anxiety Coding Schedule in order to measure anxious behavior in both child and parent, and the antecedents and consequences each provided the other to occasion anxiety in the other. This schedule was developed following the observation that children learned to process information about threat cues through interactions with their parents. More specifically, they observed that anxious children tended to view "neutral" situations as more threatening after discussing the situations with their parents than they did in the absence of such interactions. To learn more about how this happened, Dadds and colleagues observed the moment-to-moment process whereby parents of anxious children influenced their children to change from a nonthreatened stance to an avoidant, threatened stance. To examine the interdependency of the parents and the child, they coded each family member's utterances in real time sequence so that conditional probabilities could be computed between different family members' behaviors. Using this system, they were able to show the process by which, and through which, the anxiety response was activated and maintained in the child. Thus a very complicated process of parent–child interactions was broken down into its constituent parts, recorded with a sophisticated observation system, and analyzed sequentially over time. Moreover, the observations suggested that, in this sample of overanxious children, anxiety did not exist solely "in" the child; rather, it existed in a context that was highly dependent upon parental influences. Such a demonstration illustrates the importance of contextual influences in understanding, assessing, and treating diverse child behavior disorders.

In sum, direct behavioral observation—either in the natural or simulated environment—provides valuable information for child behavioral assessment. When combined with information gathered through behavioral interviews, self- and other-reports, and self-monitoring, a comprehensive picture of children and their behaviors, as well as their controlling variables, is obtained. As with other assessment procedures, however, direct behavioral observation alone is not sufficient to meet the various behavioral assessment functions required for a thorough analysis of a child's problem behavior.

4.06.5 RESEARCH FINDINGS

As noted earlier, use of assessment instruments and procedures that have been empirically validated is one of the primary characteristics of child behavioral assessment. However, the role of conventional psychometric standards in evaluating child behavioral assessment procedures is a controversial one (e.g., Barrios & Hartman, 1986; Cone, 1981, 1986; Cone & Hawkins, 1977; Mash & Terdal, 1981). Given the theoretical underpinnings of child behavioral assessment and the basic assumptions regarding situational specificity and temporal instability of behavior, traditional psychometric standards would appear to be of little or no value. After all, how can behaviors thought to be under the control of specific antecedent and consequent events be expected to be similar in different settings and at different times? Yet, if there is no consistency in behavior across settings and time, prediction of behavior is impossible and the generalizability of findings obtained from any one method of assessment would be meaningless. Such an extreme ideographic stance precludes meaningful assessment, except of highly discrete behaviors in very specific settings and at very specific points in time (Ollendick & Hersen, 1984).

Research findings suggest that it is not necessary totally to dismiss notions of cross-situational and cross-temporal consistency of behavior (e.g., Bem & Allen, 1974). Although a high degree of behavioral consistency cannot be expected, a moderate degree of behavioral consistency can be expected across situations that involve similar stimulus and response characteristics and are temporally related. When multimethod assessment procedures are used under these conditions, a modest relationship among the measures and a fair degree of predictability and generalizability can be expected. Under such circumstances, application of conventional psychometric standards to evaluation of child behavioral assessment procedures is less problematic and potentially useful (Cone, 1977; Ollendick & Hersen, 1984, 1993). The value of psychometric principles has already been demonstrated for certain classes of behavior when obtained through methods such as behavioral observation (e.g., Olweus, 1979), self-report (e.g., Ollendick, 1981), and other-report ratings (e.g., Cowen, Pederson, Barbigian, Izzo, & Trost, 1973). Further, when multiple methods of behavioral assessment have been used in the same studies, a modest degree of concurrent and predictive validity has been reported (e.g., Gresham, 1982).

It is beyond the scope of the present chapter to review specific research findings related to the reliability, validity, and clinical utility of the various procedures espoused in the multimethod approach. Nonetheless, brief mention will be made of specific directions of research and ways of enhancing the psychometric qualities of each procedure.

4.06.5.1 Behavioral Interviews

As noted by Evans and Nelson (1977), data based on retrospective reports obtained during the interview may possess both low reliability (agreement among individuals interviewed may differ and responses may vary over time) and low validity (reported information may not correspond to the "facts"). Such inaccurate or distorted recollections may result not only in delayed clarification of the presenting complaints, but also in faulty hypotheses about causal agents and maintaining factors. For example, Chess, Thomas, and Birch (1966) reported that parents inaccurately reported certain behavior problems developed at times predicted by popular psychological theories. For example, problems with siblings were recalled to have begun with the birth of a younger sibling, and problems with dependency were reported to have begun when the mother became employed outside the home. In actuality, these behaviors were present prior to these events; nonetheless, they were "conveniently" recalled to have begun coincident with commonly accepted "life" points. In a similar vein, Schopler (1974) noted that many parents of autistic children inaccurately blame themselves for their child's problematic behaviors and that many therapists inadvertently "buy into" this notion that parents are to blame. Such scapegoating accomplishes little in the understanding, assessment, and treatment of the child's problematic behavior (Ollendick & Cerny, 1981).

While the reliability and validity of general information about parenting attitudes and practices are suspect, findings suggest parents and children can be reliable and valid reporters of current, specific information about problematic behaviors (e.g., Graham & Rutter, 1968; Gross, 1984; Herjanic, Herjanic, Brown, & Wheatt, 1973). The reliability and validity of the information are directly related to recency of behaviors being discussed and specificity of information requested. Thus, careful specification of precise behaviors and conditions under which they are occurring is more reliable and valid than vague descriptions of current behaviors or general recollections of early childhood events (Ciminero & Drabman, 1977). When the interview is conducted along such guidelines, it is useful in specifying behaviors of clinical interest and in determining appropriate therapeutic interventions. As we have noted, however, it is only the first step in the ongoing, hypothesis-generating process that is characteristic of child behavioral assessment.

4.06.5.2 Ratings and Checklists

As with behavioral interviews, issues related to reliability and validity are also relevant to ratings and checklists. Cronbach (1960) has noted that the psychometric quality of rating scales is directly related to the number and specificity of the items rated. Further, O'Leary and Johnson (1986) have identified four factors associated with item-response characteristics and raters that enhance reliability and validity of such scales: (i) the necessity of using clearly defined reference points on the scale (i.e., estimates of frequency, duration, or intensity), (ii) the inclusion of more than two reference points on the scale (i.e., reference points that quantify the behavior being rated), (iii) a rater who has had extensive opportunities for observing the child being rated, and (iv) more than one rater who has equal familiarity with the child.

The rating forms and checklists described earlier (e.g., Revised Behavior Problem Checklist, Child Behavior Checklist, Behavior Assessment System for Children, the Louisville Fear Survey Schedule for Children, and the Home Situations Questionnaire) incorporate these item and response characteristics and are generally accepted as reliable and valid instruments. For example, the interrater reliability of the Revised Behavior Problem Checklist is quite high when raters are equally familiar with the children being rated and when ratings are provided by raters within the same setting (Quay, 1977; Quay & Peterson, 1983). Further, stability of these ratings has been reported over two-week and one-year intervals. These findings have been reported for teachers in the school setting and parents in the home setting. However, when ratings of teachers are compared to those of parents, interrater reliabilities are considerably lower. While teachers seem to agree with other teachers, and one parent tends to agree with the other parent, there is less agreement between parents and teachers. Such differences may be due to differential perceptions of behavior by parents and teachers or to the situational specificity of behavior, as discussed earlier (also see Achenbach et al., 1987). These findings support the desirability of obtaining information about the child from as many informants and from as many settings as possible.

The validity of the Revised Behavior Problem Checklist has also been demonstrated in numerous ways. It has been shown to distinguish clinic-referred children from nonreferred children, and to be related to psychiatric diagnosis, other measures of behavioral deviance, prognosis, and differential effectiveness of specific treatment strategies (see Ollendick & Cerny, 1981, for a discussion of these findings).

Findings similar to these have been reported for the Child Behavior Checklist, Behavior Assessment System for Children, Louisville Fear Survey Schedule, and the Home Situations Questionnaire. These rating forms and checklists, as well as others, have been shown to possess sound psychometric qualities and to be clinically useful. They not only provide meaningful data about the child's adaptive and problem behaviors but are also useful in orienting parents, teachers, and significant others to specific problem or asset areas and in alerting them to observe and record specific behaviors accurately and validly.

4.06.5.3 Self-report Instruments

Of the various methods used in child behavioral assessment, the self-report method has received the least empirical support, although this picture is rapidly changing. As noted earlier, child behavioral assessors initially eschewed use of self-report instruments, largely on the basis of their suspected low reliability and validity. As we have noted, however, data from self-report instruments can be meaningfully used to understand and describe the child, plan treatment, and evaluate treatment outcome.

As with interview and checklist or rating data, self-report of specific behaviors (including cognitions and affects) and events is more reliable and valid than more general, global reports of life experiences. Such self-reports of specific states can be used to identify discrete components of more general constructs (e.g., determining the exact fears of a phobic child and the exact situations that are associated with withdrawn behavior in an unassertive child). Illustratively, Scherer and Nakamura's (1968) Fear Survey Schedule for Children and its revision. (Ollendick, 1983b) can be used to pinpoint specific fears and classes of fear. Further, this instrument has been shown to be reliable over time, to possess high internal consistency and a meaningful and replicable factor structure, to distinguish between phobic and nonphobic children, and to discriminate among subtypes of phobic youngsters within a particular phobic group (Ollendick & Mayer, 1984; Ollendick, King, & Yule, 1994).

Clearly, more research is needed in this area before routine use of self-report instruments can be endorsed. Nonetheless, instruments that measure specific aspects of behavior such as anxiety or depression rather than global traits hold considerable promise for child behavioral assessment.

4.06.5.4 Self-monitoring

In self-monitoring, children observe their own behavior and then systematically records its occurrence. As with other measures, concerns related to the reliability and validity of this method exist. What is the extent of interobserver agreement between children who are instructed to monitor their own behavior and objective observers? How accurate are children in recording occurrences of behavior? How reactive is the process of self-monitoring?

The literature in this area is voluminous. Even though all necessary studies have not been conducted, the findings are in general agreement. First, children as young as seven years of age can be trained to be reliable and accurate recorders of their own behavior. However, the specific behaviors should be clearly defined, prompts to self-record should be available, and reinforcement for self-monitoring should be provided. Under such conditions, children's recordings closely approximate those obtained from observing adults. For example, in a study examining the effects of self-monitoring and self-administered overcorrection in the treatment of nervous tics in children, Ollendick (1981) showed that 8–10-year-old children who were provided clear prompts to self-record highly discrete behaviors were able to do so reliably. Estimates of occurrence closely paralleled those reported by parents and teachers, even though children were unaware that these adults were recording their nervous tics. In another study, Ackerman and Shapiro (1985) demonstrated the accuracy of self-monitoring by comparing self-recorded data with a permanent product measure (the number of units produced in a work setting). Again, accuracy of self-monitoring was confirmed.

Second, self-monitoring may result in behavior change due to the self-observation process and result in altered estimates of target behaviors. This effect is known as reactivity. Numerous factors have been shown to influence the occurrence of reactivity: specific instructions, motivation, goal-setting, nature of the self-recording device, and the valence of the target behavior (e.g., Nelson, 1977, 1981). Among the more important findings are that desirable behaviors (e.g., study habits, social skills) may increase while undesirable behaviors (e.g., nervous tics, hitting) tend to decrease following self-monitoring, and that the more obtrusive the self-recording device, the greater the behavior change. For example, Nelson, Lipinski, and Boykin (1978) found that hand-held counters produced greater reactivity than belt-worn counters. Holding a counter in one's hand was viewed as more obtrusive, contributing to increased reactivity. Reactivity is a concern in the assessment process because it affects the actual occurrences of behavior. However, if one is aware of the variables that contribute to reactive effects, self-monitoring can be used as a simple and efficient method for data collection (Shapiro, 1984).

In short, self-monitoring has been found to be useful in the assessment of a wide range of child behavior problems across a wide variety of settings. When issues related to the reliability, accuracy, and reactivity of measurement are addressed, self-monitoring represents another clinically useful strategy that is highly efficient and clinically useful.

4.06.5.5 Behavioral Observation

As with other assessment strategies, behavioral observation procedures must possess adequate psychometric qualities and be empirically validated before their routine use can be endorsed. Although early behaviorists accepted the accuracy of behavioral observations based on their face validity, subsequent investigators enumerated a variety of problems associated with their reliability, validity, and clinical utility (e.g., Johnson & Bolstad, 1973; Kazdin, 1977). These problems include the complexity of the observation code, the exact recording procedures to be used (e.g., frequency counts, time sampling, etc.), observer bias, observer drift, and the reactive nature of the observation process itself (see Barton & Ascione, 1984, for further discussion of these issues). Our experience suggests that the greatest threat to the utility of observational data comes from the reactive nature of the observational process itself, especially when the observer is present in the natural setting. It is well known that the presence of an observer affects behavior, usually in socially desirable directions. We have found two strategies to be useful in reducing such reactive effects: recruiting and training observer-coders already present in the natural setting (e.g., a teacher or parent), and if this is not possible, planning extended observations so children can habituate to the observers and so that the effects of reactivity will diminish. However, in the latter instance, it should be noted that several sessions of observations may be required, since reactive effects have been observed to be prolonged (Johnson & Lobitz, 1974). Reactive effects, combined with the aforementioned practical issues of personnel, time, and resources, have led us to place greater emphasis on recruiting observer-coders already in the children's natural environment or training children themselves to record their own behavior.

In brief, behavioral observations are the most direct and least inferential method of assessment. Even though a variety of problems related to their reliability and validity have been commented upon, behavioral observations are highly useful strategies and represent the hallmark of child behavioral assessment. Whenever possible, behavioral observations in the natural setting should be obtained.

4.06.6 FUTURE DIRECTIONS

A number of directions for future research and development in child behavioral assessment may be evident to the reader. What follows is our attempt to highlight those areas that appear most promising and in need of greater articulation.

4.06.6.1 Developmental Factors

First, it seems to us that greater attention must be given to developmental factors as they affect the selection of child behavioral assessment procedures. Although we have argued that these procedures should be developmentally sensitive, child behavioral assessors have frequently not attended to, or have ignored, this recommendation. As we noted earlier, the most distinguishing characteristic of children is developmental change. Such change encompasses basic biological growth and maturity as well as affective, behavioral, and cognitive fluctuations that may characterize children at different age levels. While the importance of accounting for developmental level when assessing behavior may be obvious, ways of integrating developmental concepts and principles into child behavioral assessment are less evident. Edelbrock (1984) has noted three areas for the synthesis of developmental and behavioral principles: (i) use of developmental fluctuations in behavior to establish normative baselines of behavior, (ii) determination of age and gender differences in the expression and covariation of behavioral patterns, and (iii) study of stability and change in behavior over time. Clearly, these areas of synthesis and integration are in their infancy and in need of greater articulation (e.g., Harris & Ferrari, 1983; Ollendick & Hersen, 1983; Rutter & Garmezy, 1983; Sroufe & Rutter, 1984).

Recently, Ollendick and King (1991) addressed this developmental–behavioral synthesis in some detail. In reference to normative data, they suggested that such information could be used to determine which behavior problems represent clinically significant areas of concern, examine appropriateness of referral, and evaluate efficacy of interventions. Essentially, this normative-developmental perspective emphasizes the central importance of change over time and the need for relevant norms against which children can be compared, both at the time of assessment and following treatment. Another way in which developmental principles can be integrated into ongoing child behavioral assessment is to identify age differences in the relations or patterns among behaviors (Edelbrock, 1984). Ollendick and King (1991) have shown such patterning of behavior across development for a number of measures, including diagnostic interviews, self- and other-report instruments, and behavioral coding systems.

Finally, developmental principles can be useful in child behavioral assessment in our attempts to examine and understand continuity and discontinuity of certain behavioral patterns. Basically, this issue can be addressed from two vantage points, a descriptive one and an explanatory one. From a descriptive standpoint, we are interested in determining whether a behavior or set of behaviors seen at one point in time can be described in the same way at another point in time. If it can be described in the same way, descriptive continuity is said to exist; if it cannot, descriptive discontinuity is said to obtain (Lerner, 1986). We are simply asking, does the behavior look the same or different? Does it take the same form over time? For example, if 4-year-old, 8-year-old, and 12-year-old children all emitted the same behaviors to gain entry in a social group, we would conclude that descriptive continuity exists for social entry behavior.

For the most part, it has been shown that the expression and patterning of a large number of behaviors change across development and that descriptive discontinuity is more likely the case (Ollendick & King, 1991). Changes in behavior observed with development can, of course, occur for many different reasons. If the same explanations are used to account for behavior over time, then that behavior is viewed as involving unchanging laws or rules and explanatory continuity is said to exist. However, if different explanations are used to account for changes in behavior over time, explanatory discontinuity prevails (Lerner, 1986). For the most part, behaviorally oriented theorists and clinicians maintain changes over time are due to a set of learning principles that are largely the same across the child's life span. No new principles or laws are needed as the child grows. Developmental theorists, on the other hand, maintain a progressive differentiation of the organism which suggests a different set of principles be invoked across different stages of development. Unfortunately, the evidence on explanatory continuity versus discontinuity is scarce; the jury is out on these issues. Much work remains to be done in this area; however, as Ollendick and King (1991) note, the emergence of "developmental–behavioral assessment" is on the horizon.

4.06.6.2 The Utility of the Multimethod Approach at Different Age Levels

Second, and somewhat related to the first area, greater attention must be focused on the incremental validity of the multimethod approach when used for children of varying ages. Throughout this chapter, we have espoused a multimethod approach consisting of interviews, self- and other-reports, self-monitoring, and behavioral observations. Some of these procedures may be more appropriate at some age levels than others. Further, the psychometric properties of these procedures may vary with age. For example, self-monitoring requires the ability to compare one's own behavior against a standard and accurately to judge occurrence or nonoccurrence of targeted events and behaviors. Most children below six years of age lack the requisite ability to self-monitor and may not profit from such procedures. In fact, the limited research available suggests self-monitoring may be counter-productive when used with young children, resulting in confusion and impaired performance (e.g., Higa, Thorp, & Calkins, 1978). These findings suggest that self-monitoring procedures are better suited for children who possess sufficient cognitive abilities to benefit from their use (Shapiro, 1984). In a similar vein, age-related variables place constraints on use of certain self-report and sociometric measures with young children. It has often been noted that sociometric devices must be simplified and presented in pictorial form to children under six years of age (Hops & Lewin, 1984). The picture-form sociometric device provides young children with a set of visual cues regarding children to be rated and, of course, does not require them to read names of children being rated. The roster-and-rating method, used so frequently with older children, is simply not appropriate with younger children. Ollendick and Hersen (1993) review additional age-related findings for other procedures and suggest caution in using these procedures without due regard for their developmental appropriateness and related psychometric properties.

If certain procedures are found to be less reliable or valid at different age levels, their indiscriminate use with children can not be endorsed. Inasmuch as these strategies are found to be inadequate, the combination of them in a multimethod approach would serve only to compound their inherent limitations (Mash & Terdal, 1981). The sine qua non of child behavioral assessment is that the procedures be empirically validated. In addition, the different procedures might vary in terms of their treatment utility across different ages. Treatment utility refers to the degree to which assessment strategies are shown to contribute to beneficial treatment outcomes (Hayes et al., 1987). More specifically, treatment utility addresses issues related to the selection of specific target behaviors and to the choice of specific assessment strategies. For example, we might wish to examine the treatment utility of using self-report questionnaires to guide treatment planning, above and beyond that provided by direct behavioral observation of children who are phobic of social encounters. All children could complete a fear schedule and be observed in a social situation, but the self-report data for only half of the children would be made available for treatment planning. If the children for whom self-reports were made available improved more than those whose treatment plans were based solely on behavioral observations, then the treatment utility of using self-report data would be established (for this problem with this age child). In a similar fashion, the treatment utility of interviews, role plays, and other devices could be evaluated (Hayes et al., 1987). Of course, it would be important to examine treatment utility from a developmental perspective as well. Certain procedures might be shown to possess incremental validity at one age but not another. Although the concept of treatment utility is relatively new, it shows considerable promise as a strategy to evaluate the incremental validity of our multimethod assessment approach. We should not necessarily assume that "more" assessment is "better" assessment.

4.06.6.3 Cultural Sensitivity

Considerable energy must be directed to the development of child behavioral assessment methods that are culturally sensitive. Numerous observers have called attention to the internationalization of the world and the "browning of America" (e.g., Malgady, Rogler, & Constantino, 1987; Vasquez Nuttall, DeLeon, & Del Valle, 1990). In reference to this chapter, these developments suggest that the assessment process is increasingly being applied to non-Caucasian children for whom English is not the primary language in America, and that many procedures developed in America and other Western countries are being applied, sometimes indiscriminately, in other countries as well. Development of assessment procedures that are culture-fair (and language-fair) is of utmost importance. Of course, many cultural issues need to be considered in the assessment process. Cultural differences may be expressed in child-rearing practices, family values, parental expectations, communication styles, nonverbal communication patterns, and family structure and dynamics (Vasquez et al., 1990). As an example, behaviors characteristic of ethnic minority children may be seen as emotionally or behaviorally maladaptive by persons who have little or no appreciation for cultural norms (e.g., Prewitt-Diaz, 1989). Thus, cultural differences (biases?) are likely to occur early in the assessment process. Fortunately, Vasquez-Nuttall, Sanchez, Borras Osorio, Nuttall, & Varvogil (1996) have suggested several steps that can be taken to minimize cultural biases in the assessment process.

Vasquez et al. (1996) have offered the following suggestions: (i) include extended family members in the information-gathering process; (ii) use interpreters, if necessary, in interviewing the child and family members; (iii) familiarize oneself with the culture of specific groups; and (iv) use instruments that have been translated into the native language of the children and for which norms are available for specific ethnic groups. With regard to this latter recommendation, significantly greater progress has been witnessed for the translation component than the establishment of well-standardized normative information. For example, while the Conners' Parent Rating Scales (Conners, 1985) and Conners' Teacher Rating Scale (Conners, 1985) have been translated into Spanish and other languages, group norms are lacking and the reliability and validity of the translations have not been examined systematically. Similarly, the Fear Survey Schedule for Children-Revised (Ollendick, 1983b) has been translated into over 10 languages, yet normative data are lacking and the psychometric properties of the instrument have not been fully explored or established. In sum, a clear challenge before us in the years ahead is to attend to important cultural factors that impinge on our assessment armamentarium, and to develop and promulgate culturally sensitive methods that are developmentally appropriate and empirically validated.

4.06.6.4 Measures of Cognitive and Affective Processes

More effort must be directed toward the development of culturally relevant, developmentally sensitive, and empirically validated procedures for assessment of cognitive and affective processes in children. In recent years, child behavioral assessors have become increasingly interested in the relation of children's cognitive and affective processes to observed behaviors. The need for assessment in this area is further evidenced by the continued increase of cognitive-behavioral treatment procedures with children, a trend first observed in the late 1970s and early 1980s (e.g., Kendall, Pellegrini, & Urbain, 1981; Meador & Ollendick, 1984). As noted by Kendall et al. (1981), there is a particularly pressing need to develop procedures that can examine the very cognitions and processes that are targeted for change in these intervention efforts. For example, the reliable and valid assessment of self-statements made by children in specific situations would facilitate the empirical evaluation of cognitive-behavioral procedures such as self-instructional training and cognitive restructuring (cf. Zatz & Chassin, 1983; Stefanek, Ollendick, Baldock, Francis, & Yaeger, 1987).

4.06.6.5 The Role of the Child

We must concentrate additional effort on the role of the child in child behavioral assessment. All too frequently, "tests are administered to children, ratings are obtained on children, and behaviors are observed in children" (Ollendick & Hersen, 1984, p. ix). This process views the child as a passive responder, someone who is largely incapable of actively shaping and determining behaviors of clinical relevance. Although examination of these organismic variables is only beginning, it would appear that concerted and systematic effort must be directed to their description and articulation. For example, children's conceptions of their own behavior is a critical area of further study. To what causes do children attribute aggressive or withdrawn behavior in themselves or in their peers? Are there aggregated trends in these attributions? Do they differ by culture? Do causal attributions (as well as self-efficacy and outcome expectancies) mediate treatment outcomes? Again, are there age-related effects for these effects or culturally relevant effects? The answers to these questions are of both theoretical interest and applied clinical significance.

The process described above also implies that child behavior (problematic or otherwise) occurs in a vacuum, and that the perceptions and behaviors of referral sources (parents, teachers) and characteristics of the environments in which behavior occurs are somehow less critical to assess. Recent efforts to develop reliable methods for assessing parent–child interactions are indicative of an increased awareness of the need to broaden the scope of assessment to include specific individuals with whom, and environments in which, child behavior problems commonly occur (cf. Dadds et al., 1994; Dumas, 1989; Greene, 1995, 1996; Ollendick, 1996). However, much additional work remains to be done in this area.

4.06.6.6 Ethical Guidelines

Finally, we must continue to focus our attention on ethical issues in child behavioral assessment. A number of ethical issues regarding children's rights, proper and legal consent, professional judgment, and social values are raised in the routine practice of child behavioral assessment (Rekers, 1984). Are children capable of granting full and proper consent to a behavioral assessment procedure? At what age and in what cultures are children competent to give such consent? Is informed consent necessary? Or might not informed consent be impossible, impractical, or countertherapeutic in some situations? What ethical guidelines surround the assessment procedures to be used? Current professional guidelines suggest our procedures should be reliable, valid, and clinically useful. Do the procedures suggested in this chapter meet these professional guidelines? What are the rights of parents and of society? It should be evident from these questions that a variety of ethical issues persists. Striking a balance between the rights of parents, society, and children is no easy matter but is one that takes on added importance in the increasingly litigious society of the USA.

In short, future directions of child behavioral assessment are numerous and varied. Even though a technology for child behavioral assessment has evolved and is in force, we need to begin to explore the issues raised before we can conclude the procedures are maximally productive and in the best interests of children throughout the world.

4.06.7 SUMMARY

Child behavioral assessment strategies have been slow to evolve. Only recently has the chasm between child behavior therapy and child behavioral assessment been narrowed. Increased awareness of the importance of developing assessment procedures that provide an adequate representation of child behavior disorders has spurred research into assessment procedures and spawned a plethora of child behavioral assessment techniques. The growing sophistication of child behavior assessment is witnessed by the appearance of self- and other-report strategies that are beginning to take into account developmental, social, and cultural influences as well as cognitive and affective mediators of overt behavior. At the same time, attention to psychometric properties of assessment procedures has continued.

Certain theoretical assumptions guide child behavioral assessment. Foremost among these is the premise that behavior is a function of situational determinants and not a sign of underlying personality traits. To assess adequately the situational determinants and to obtain as complete a picture of the child as is possible, a multimethod assessment approach is recommended, utilizing both direct and indirect methods of assessment. Direct methods include self-monitoring as well as behavioral observation by trained observers in naturalistic or simulated analogue settings. Indirect measures include behavioral interviewing and self- and other-report measures. These sources of information are considered indirect ones because they involve retrospective reports of previous behavior.

Even though direct behavioral observation remains the hallmark of child behavioral assessment, information from these other sources is considered not only valuable but integral in the understanding and subsequent treatment of child behavior disorders. Hence, whereas identification and specification of discrete target behaviors were once considered sufficient, current child behavioral assessment involves serious consideration and systematic assessment of cognitive and affective aspects of the child's behavior and of developmental, social, and cultural factors that influence the child, as well as direct observation of the problematic behavior *in situ*.

Several areas of future research remain. These include clearer specification of developmental variables, a closer examination of the utility of the multimethod approach at different age levels, the influence of culture and the need for models of assessment that take cultural forces into consideration, development of specific measures to examine cognitive and affective processes in children, articulation of the role of the child in child behavioral assessment, and continued development of ethical guidelines. While the basis for a technology of child behavioral assessment exists, considerable fine-tuning remains to be done. Child behavioral assessment is at a critical crossroad in its own development; which path it takes will determine its long-term future.

4.07.6 BEHAVIORAL AND PERSONALITY ASSESSMENT 180

4.07.7 SUMMARY 181

4.07.8 REFERENCES 182

4.07.1 INTRODUCTION

Psychological assessment is the systematic evaluation of a person's behavior. The components of psychological assessment include the variables selected for measurement (e.g., beliefs, social behaviors), the measurement methods used (e.g., interviews, observation), the reduction and synthesis of derived data (e.g., whether summary scores are calculated for a questionnaire), and the inferences drawn from the data (e.g., inferences about treatment effectiveness). Psychological assessment affects the evolution of all social, cognitive, and behavioral science disciplines. The accuracy with which variables can be measured affects the degree to which relationships among behavioral, cognitive, environmental, and physiological events can be identified and explained. For example, our understanding of the impact of traumatic life stressors on immune system functioning, the relationship between depressed mood and self-efficacy beliefs, the effect of social response contingencies on self-injurious behavior, and the degree to which presleep worry moderates the impact of chronic pain on sleep quality depends on the strategies we use to measure these constructs.

Psychological assessment also affects clinical judgments. In adult treatment settings, clinical psychologists make judgments about a client's risk of suicide, whether treatment is warranted for a client, whether a client should be hospitalized, the variables that affect a client's behavior problems, and the best strategy for treating a client. Psychological assessment also helps the clinician select intervention goals and evaluate intervention effects.

There are many paradigms in psychological assessment. A psychological assessment paradigm is composed of a coherent set of assessment principles, values, assumptions, and methods of assessment. It includes assumptions about the relative importance of different types of behavior problems, the variables that most likely cause behavior problems, the most likely mechanisms through which causal variables operate, the importance and role of assessment in treatment design, and the best methods and strategies of assessment. A psychological assessment paradigm also includes guidelines for problem-solving, decision-making strategies, and data interpretation.

One powerful and evolving psychological assessment paradigm is behavioral assessment (Haynes & O'Brien, in press). Influenced by behavior-analytic, social-learning, and cognitive-behavioral therapy construct systems, the paradigm incorporates diverse methods of assessment but emphasizes naturalistic and analogue observation, self-monitoring, and electrophysiological measurement. The behavioral assessment paradigm also has many methodological elements, including an emphasis on the use of minimally inferential constructs, time-series measurement, hypotheses testing, and an idiographic (i.e., focus on an individual client) approach to assessment.

This chapter focuses on clinical applications of behavioral assessment with adults. The chapter will outline the conceptual and methodological elements of behavioral assessment and indicate how they aid clinical judgment and decision-making with adult clients. To illustrate the underlying assumptions, methods, and strategies of behavioral assessment, the first section presents a functional analytic causal model of a client—a vector diagram of a behavioral clinical case conceptualization. Following a discussion of the principles and methods of behavioral assessment, subsequent sections briefly discuss the history of behavioral assessment and psychometric considerations. Developments in behavioral assessment and differences between behavioral and nonbehavioral assessment paradigms are also discussed.

4.07.2 CLINICAL JUDGMENTS AND FUNCTIONAL ANALYSIS IN BEHAVIORAL ASSESSMENT

One of the most important and complex clinical judgments is the clinical case conceptualization. The clinical case conceptualization is a metajudgment—it is composed of many lower-level judgments regarding a client's behavior problems and the factors that affect them. It is a synthesis of assessment- and research-based hypotheses about a client and its primary application is for designing the most effective treatment.

In behavioral assessment, clinical case conceptualization is often termed "functional analysis" (Haynes & O'Brien, 1990). (Terms with similar meanings include "clinical pathogenesis map" [Nezu & Nezu, 1989] and "behavioral case formulation" [Persons, 1989]. The term "functional analysis" is often used in applied behavior analysis to refer to the systematic manipulation of variables, in a controlled assessment setting, to deteremine their effect on designated dependent variables.) Functional analysis is a central component in the design of behavior therapy programs because of individual differences between clients—two clients can manifest the same primary behavior problem for different reasons and, consequently, receive different treatments. Behavioral interventions are often designed to modify variables that are hypothesized to affect (i.e., account for variance in, trigger, maintain, moderate) problem behaviors and goals (Haynes, Spain, & Oliveira, 1993). Many permutations of causal variables can result in identical behavior problems, thereby resulting in different functional analyses and warranting different interventions.

Behavioral interventions are designed on the basis of many judgments about a patient reflected in a functional analysis. Clinical judgments with important implications for treatment decisions include the importance (e.g., severity, degree of risk associated with) of a client's multiple behavior problems; the relationships (e.g., strength, correlational vs. causal) among a client's multiple behavior problems, and the effects of behavior problems. Judgments about causal variables that affect the behavior problem (their importance, functional form, modifiability) are particularly important elements of the functional analysis.

There can be many errors in the clinical judgments that compose a clinical case conceptualization. Books by Eels (1997), Nezu and Nezu (1989), and Turk and Salovey (1988) discuss many of these errors. In brief, a clinician's judgments about a client can be affected by the clinician's preconceived beliefs, recent or particularly salient clinical experiences, selective attention to data that confirms the clinician's expectations, training-related biases, premature diagnoses, decisions based on initial impressions, and insufficient integrative abilities. These errors can reduce the validity of the case conceptualization and reduce the chance that the most effective treatment strategy will be selected for a patient.

The supraordinate goal of behavioral assessment is to reduce error and increase the validity in clinical judgments. The behavioral assessment paradigm suggests that clinical judgment error can be reduced to the degree that the assessor uses multiple sources of information, validated assessment instruments, time-series measurement strategies, focuses on multiple response modes, minimizes the inferential characteristics of variables, addresses behavior–environment interactions, and is guided by data from previously published studies (e.g, Persons & Fresco, 1998).

Haynes (1994), Haynes et al. (1993), Nezu and Nezu (1989), and Nezu et al. (1996) have outlined two methods to help the clinician systematically integrate the complex information contained in a functional analysis. These methods are the clinical pathogenesis map and functional analytic causal models (FACMs). Both involve systematic construction of vector diagrams of the component clinical judgments in a functional analysis and are designed to promote less intuitive intervention decisions. The clinical pathogenesis map and FACMs graphically model the clinician's hypotheses about a patient's behavior problems and goals and their relative importance, interrelationships, sequela and the strength, modifiability, and direction of action of causal variables. The FACM allows the clinician to estimate, quantitatively or qualitatively, the relative magnitude of effect of a particular treatment focus, given the clinician's hypotheses about the patient.

The FACM of a client presented in Figure 1 will be used to illustrate several underlying assumptions and methods of the behavioral assessment paradigm. The graphics in Figure 1 are explained in Figure 2. The client was a 35-year-old pregnant, married, unemployed woman (Mrs. A) who came to an outpatient mental health center complaining of constant headaches and sleeping problems. (This FACM was modified from one developed by Akiko Lau, University of Hawaii and discussed in Haynes, Leisen, & Blaine, 1997.) She was referred by her neurologist and had undergone extensive neurological and endocrinological examinations with negative results.

Mrs. A was first interviewed in an unstructured, open-ended manner, with the goal of encouraging her to talk about her behavior problems, goals, and the factors affecting them (Haynes, 1978). Structured interviews were then conducted to acquire more detailed information on specific behavior problems mentioned in the unstructured interview, such as her anxiety symptoms (Brown, DiNardo, & Barlow, 1994), marital relationship concerns (O'Leary, 1987), headache (James, Thorn, & Williams, 1993), sleep disturbance (Lichstein & Riedel, 1994), and other factors depicted in Figure 1. Validated questionnaires on marital satisfaction, child behavior problems, anxiety, and life stressors were also administered to provide additional information on issues raised in the interview process.

Because headaches and sleep difficulties were important problems, Mrs. A began daily self-monitoring after the second interview and continued to self-monitor throughout the assessment-treatment process. She recorded headache intensity and symptoms four times per day and each morning she recorded sleep-onset and awakenings for the previous night.

Marital conflict was a major concern for Mrs. A and one possible cause of her psychophysiological problems. Consequently, a one and a half hour assessment session (the third session) was conducted with her and her husband. During the session, the couple underwent a

conjoint structured interview about their marital relationship (e.g., perceived conflicts, strengths, spousal excesses and deficits, marital goals), and Mr. A also completed a marital satisfaction questionnaire. The couple participated in an analogue communication assessment, in which they discussed for 10 minutes their conflicts regarding disciplining their 12-year-old daughter. The conversation was recorded and later coded by the assessor.

Based on interview and questionnaire data, conflicts with her daughter were another source of distress for Mrs. A. A joint assessment session (the fourth session) was conducted in which the daughter was interviewed about her perception of family issues. Also, the mother and daughter were observed in two structured assessment settings: while trying to resolve one of their frequent sources of conflict (the daughter's refusal to do her school work) and while Mrs. A attempted to help her daughter with some school work.

The functional analytic causal model of Mrs. A emphasizes many elements of a clinical case conceptualization that are important for behavioral treatment decisions. (Many other factors—e.g., treatment history, client cognitive resources, cost-efficiency of treatments, responses of persons in the client's environment—affect treatment design in addition to those included in a FACM.) Important and controllable functional relationships are highlighted in the FACM because of their clinical utility. The FACM for Mrs. A recognizes some unmodifiable variables but these have no clinical utility. Unidirectional and bidirectional causal relationships are shown because they can significantly affect decisions about what variables should be targeted in treatment. Treatment decisions are also affected by the strength of causal relationships and the degree of modifiability of causal variables, depicted in Figure 1.

Before considering the specific assumptions of the behavioral assessment paradigm that influenced the assessment strategy outlined above and the clinical judgments summarized in Figure 1, several additional attributes of the functional analysis should be briefly noted. First, the functional analysis (and the FACM) reflects the clinician's current judgments about a client. It is a subjectively derived (although data-influenced), hypothesized model. It is also unstable, in that it can change with changes in naturally occurring causal variables, with the acquisition of additional data, and as a result of treatment. For example, a change in the variables that affected Mr. A's drinking could lead to a significant change in the FACM for Mrs. A. A FACM for a client may be conditional. For example, some variables affecting Mrs. A's behavior problems may change after the birth of her child.

A final note on the limitations of the functional analysis. Despite its central role in behavior therapy, the functional analysis is limited in several ways: (i) the best assessment methods for developing a functional analysis have not been identified, (ii) the best methods for formulating a functional analysis from assessment data have not been determined, and (iii) for many behavior problems, the incremental utility and cost-effectiveness of the functional analysis have yet to be established.

4.07.3 CONCEPTUAL FOUNDATIONS OF BEHAVIORAL ASSESSMENT

Many methodological elements of the behavioral assessment paradigm, such as the preferred methods of assessment and the variables targeted in assessment, are influenced by its underlying assumptions. The following sections review two sets of assumptions: (i) those concerning the causal factors associated with behavior problems and goals, and (ii) those concerning the characteristics of behavior problems. This section also discusses implications of these assumptions for behavioral assessment strategies with adults. More extensive discussions of underlying assumptions in behavioral assessment can be found in Bandura (1969), Barrios (1988), Bellack and Hersen, (1988), Bornstein, Bornstein, and Dawson (1984), Ciminero, Calhoun, and Adams (1986), Cone (1988), Eysenck, (1986), Haynes (1978), Hersen and Bellack (1998), Johnston and Pennypacker, (1993), Kratochwill and Shapiro (1988), Mash and Terdal (1988), Nelson and Hayes (1986), O'Donohue and Krasner, (1995), Ollendick and Hersen (1984, 1993), Strosahl and Linehan (1986), and Tryon (1985).

4.07.3.1 Assumptions About the Causes of Behavior Disorders

Psychological assessment paradigms differ in the assumptions they make regarding the causes of behavior disorders. Although causal assumptions and the identification of causal variables in pretreatment assessment are less important for treatment paradigms with limited treatment options (e.g., Gestalt, transactional therapies), the identification of potential causal variables is a primary objective in pretreatment behavioral assessment. This is because hypothesized controlling variables are targeted for modification in behavior therapy and it is presumed that causal variables may vary across patients with the same behavior problems. The variables presumed to cause Mrs. A's sleep problems may not operate for other patients with identical sleep problems. Consequently, other patients with the same sleep disorder would be treated differently.

Behavioral assessment strategies are guided by several empirically based and interrelated assumptions about the causes of behavior problems. These assumptions include: multiple causality, multiple causal paths, individual differences in causal variables and paths, environmental causality and reciprocal determinism, contemporaneous causal variables, the dynamic nature of causal relationships, the operation of moderating and mediating variables, interactive and additive causality; and situations, setting events, and systems factors as causal variables and dynamical causal relationships.

4.07.3.1.1 Multiple causality

Behavior problems are often the result of multiple causal variables acting additively or interactively (Haynes, 1992; Kazdin & Kagan, 1994). This is illustrated in Figure 1 by the multiple factors influencing Mrs. A's headaches. Although some behavior problems and the behavior problems of some individuals (e.g., asthma episodes that are mostly triggered by exposure to specific allergens) may primarily be the result of single causal variables, multivariate causal models have been proposed for most adult behavior disorders, including schizophrenia, chronic pain, sleep disorders, paranoia, personality disorders, child abuse, and many other behavior disorders (see reviews in Gatchel & Blanchard, 1993; Sutker & Adams, 1993).

4.07.3.1.2 Multiple causal paths

A causal variable may also affect a behavior problem through multiple paths. Note that for Mrs. A, physiological hyperreactivity can directly influence sleep but hyperreactivity can also influence sleep because it produces headaches. Similarly, there may be many paths through which social isolation increases the risk of depression (e.g., by restricting the potential sources of social reinforcement, by increasing dependency on reinforcement from a few persons) and many paths through which immune system functioning can be impaired by chronic life stressors (e.g., dietary changes, reduction of lymphocyte levels).

4.07.3.1.3 Individual differences in causal variables and paths

Models of causality for behavior problems are further complicated because the permutations of causal variables and causal mechanisms can differ across clients with the same behavior problem. For example, there can be important differences in the causal variables and causal paths among persons reporting chronic pain (Waddell & Turk, 1992), exhibiting self-injurious behaviors (Iwata et al., 1994), or who complain of difficulties in initiating and maintaining sleep (Lichstein & Riedel, 1994). Some differences in causality may covary with dimensions of individual differences. For example, the causes of depression, marital distress, and anxiety may vary as a function of ethnicity, age, gender, religion, sexual orientation, and economic status (see discussions in Marsella & Kameoka, 1989).

4.07.3.1.4 Environmental causality and reciprocal determinism

The behavioral assessment paradigm also stresses the importance of environmental causality and behavior–environment interactions (McFall & McDonel, 1986). Many studies have shown that it is possible to account for variance in many behavior problems by examining variance in response contingencies (e.g., how others respond to self-injurious behaviors, depressive statements, or asthma episodes can affect the parameters of those behaviors—a "parameter" of a behavior refers to a quantitative dimension, such as rate, duration, magnitude, and cyclicity), situational and antecedent stimulus factors (e.g., alcohol use may vary reliably across social settings, anxiety episodes may be more likely in more interpersonally stressful environments), and other learning principles (e.g., modeling, stimulus pairings; see discussions in Eysenck & Martin, 1987; O'Donohue & Krasner, 1995).

An important element of the principle of environmental causality is reciprocal determinism, (i.e., bidirectional causality, reciprocal causation; Bandura, 1981)—the idea that two variables can affect each other. In a clinical context, reciprocal determinism refers to the assumption that clients can behave in ways that affect their environment which, in turn, affects their behavior. For example, a client's depressive behaviors (e.g., reduced social initiations and positive talk) may result in the withdrawal of the client's friends, increasing the client's loss of social reinforcement and increasing the client's depressive mood and behaviors. A hospitalized paranoid patient may behave suspiciously with staff and other patients. These behaviors may cause others to avoid the patient, talk about him/her and behave in many other ways that confirm and strengthen the patient's paranoid thoughts. With Mrs. A, we presume that there are some ways that Mrs. A is behaving that might contribute to her marital distress and difficulties. An emphasis on bidirectional causation does not negate the possibility of unidirectional environmental causal factors. In some distressed marriages, for example, a spouse may independently be contributing to marital distress by being verbally abusive or unsupportive. However, pure unidirectional causation may be rare.

Viewing clients within a reciprocal determinism framework effects the focus of assessment and treatment. Clients are considered active participants in their own lives, as active contributors to their goal attainment and to their behavior problems. Consequently, clients are encouraged to participate actively in the assessment–treatment process. Assessment goals include identifying the ways that clients may be contributing to their behavior problems and ways they can contribute to the attainment of treatment goals.

One consequence of reciprocal determinism is that labels such as "behavior problem (dependent variable)" or "causal variable (independent variable)" become less distinct. Often, either variable in a bidirectional relationship can be described as a behavior problem and a causal variable—each variable can be either or both. Which variables are described as problem vs. cause depends more on convention or the intent of the assessor and client than on the characteristic of the functional relationships. As indicated in the functional analytic causal models (e.g., Haynes, 1994), treatment decisions are dictated more by estimates of the strength of causal relationships than by the label of the variable.

The concept of reciprocal determinism also promotes a behavioral skills focus in assessment and treatment. A client's behavior problems are presumed to be a partial function of their behavioral repertoire. Their behavioral excesses, deficits, and strengths are presumed to affect whether they will experience problems in some situations, the type and magnitude of behavior problem experienced and how long the problem persists. For example, a behavior skills assessment with a socially anxious client might focus on specific deficits that prevent the client from forming more frequent and satisfying friendships. Similar to a task analysis, the necessary skills for attaining a treatment goal (e.g., establishing positive friendships) are broken down into molecular components and the client's abilities on these components are evaluated. With Mrs. A, it would be important to determine what additional parenting and marital communication skills might help Mrs. A develop a more positive relationship with her daughter and husband. An example would include the ability to clearly and positively talk about her ideas and concerns.

Cognitive skills are often targeted by behavioral assessors. The clients' beliefs, expectancies, deductions, and other thoughts regarding their capabilities in specific situations (e.g., Linscott & DiGiuseppe, 1998) are often considered essential elements for effective functioning. A molar-level skill is adaptive flexibility—an overarching goal of behavior therapy is to help the client to develop behavior repertoires that facilitate adaptability to various, novel and changing environments.

4.07.3.1.5 Contemporaneous causal variables

The behavioral assessment paradigm emphasizes the relative importance and utility of contemporaneous rather than historical, causal factors. It is presumed that a more clinically useful, and sometimes more important, source of variance in a client's behavior problems can be identified by examining the client's current, rather than historical, learning experiences, social contingencies, and thoughts. For example, suspicious thoughts and behaviors can undoubtedly be learned as a child from parental models (e.g., parents who teach a child to be mistrustful of others' intentions; Haynes, 1986). However, early parent–child learning experiences are difficult to identify and "treat" in therapy. Assessment efforts might more profitably be focused on contemporaneous causal variables for paranoid thoughts—such as restricted social network that precludes corrective feedback about misperceptions, social skills deficits, hypersensitivity to negative stimuli or negative scanning, or failure to consider alternative explanations for ambiguous events. These can also be important causal variables for a client's paranoid behaviors and are more amenable than historical events to intervention.

The emphasis on contemporaneous, reciprocal, behavior–environment interactions dictates an emphasis on particular methods of assessment. For example, naturalistic observation, analogue observation, and self-monitoring are better suited than retrospective questionnaires to measuring contemporaneous, reciprocal dyadic interactions. Additionally, in behaviorally oriented interviews and questionnaires clients are more often asked about current than about past behavior–environment interactions (Jensen & Haynes, 1986; Sarwer & Sayers, 1998).

An emphasis on contemporaneous reciprocal determinism is compatible with the causal role of genetic and physiological factors, and early learning experiences. Evidence from many sources suggests that genetic factors, neurophysiological mechanisms, medical disorders, and early learning (e.g., early traumatic experiences) can serve as important causal variables for behavior problems (see reviews in Asteria, 1985; Haynes, 1992; Sutker & Adams, 1993). Sometimes, physiological, behavioral, and cognitive variables are different modal expressions of the same phenomena.

The emphasis on contemporaneous behavior and environmental causality is evident in the contemporaneous focus of many behavioral assessment interviews. However, behavioral assessors differ in their emphasis on historical data. Joseph Wolpe, for example, emphasized the importance of gathering a complete clinical history for patients before therapy (Wolpe & Turkat, 1985). Often historical information can aid in the development of hypotheses regarding the time-course and causes of behavior problems. For example, a careful interview about past behaviors, events and treatment experiences can help determine if Mrs. A may be experiencing neurological deficits (e.g., she had a minor head injury two years prior to this assessment) and may help estimate the degree to which her health-related behaviors (e.g., poor diet and exercise habits) are modifiable.

4.07.3.1.6 Interactive and additive causality

In the section on multiple causality, I noted that a behavior problem often results from multiple causal factors acting concurrently—this is an additive model of causality. Causal variables can also interact—this is a multiplicative model of causality. Interactive causality occurs when the causal effects of one variable vary as a function of the values of another causal variable (see discussion in Haynes, 1992). Furthermore, the effects of the variables in combination often cannot be predicted by simply summing their independent effects. A longitudinal study by Schlundt, Johnson, and Jarrell (1986) demonstrated interactive causal effects with bulimic clients. The probability of postmeal purging was significantly related to a history of recent purges (i.e., purging tended to occur in cycles). However, the social context within which eating occurred affected the strength of the relationship between those two variables. The chance of purging was higher when the person had recently purged, but especially higher if the person ate alone. The effect of each causal variable (purging history, social context) depended on the value of the other causal variable.

Diathesis-stress models of psychopathology are common exemplars of interactive causality (e.g., Barnett & Gotlib, 1988). Diathesis-stress models suggest that environmental stressors and physiological or genetic vulnerability (or genetic and later physiological challenges) interact to affect the probability that a particular behavior disorder will occur.

4.07.3.1.7 Situations, setting events, and systems factors as causal variables

One assumption of the behavioral assessment paradigm is that the probability (or another parameter such as magnitude) of behavior problems varies across situations, settings, and antecedent stimuli (e.g., discrete and compound antecedent stimuli, contexts, discriminative stimuli for differential reinforcement contingencies); behavior problems are conditional. The conditional nature of behavior problems has important causal implications because it marks the differential operation of causal factors. Mrs. A was more likely to experience anxiety symptoms in the presence than in the absence of her daughter. The presence of the daughter marked the operation of a causal relationship and suggested to the assessor that the mother–daughter interactions should be explored in greater detail.

A situational model of behavior problems contrasts with traditional personality trait models, which emphasize a higher degree of cross-situational consistency of behavior and some enduring trait of the person as the primary causal variable for behavior problems (see subsequent discussion of personality assessment). However, situational and trait models of behavior problems can be compatible. Knowledge of the robust behaviors of a client (e.g., those behaviors that do not vary to an important degree across conditions) and knowledge of the situational factors that influence the client's behavior can both contribute to a functional analysis of the client. This "interactional" perspective is a welcomed refinement of exclusively trait models (see discussions by Mischel, 1968; McFall & McDonel, 1986).

Cross-situational consistency can vary across different behaviors, individuals, and situations; relative cross-situational consistency in behavior can occur, but may not. Because the assessor does not have prior knowledge of the degree of cross-situational consistency of a client's behavior problems, the assessor must evaluate their conditional nature. Unfortunately, strategies and classification schema for situations have not been developed.

Although the behavioral assessment paradigm emphasizes contemporaneous causal factors (e.g., a SORC [stimulus, organism, response, contingency] model; Goldfried, 1982), extended social systems can play an important causal role. Mrs. A's marital satisfaction may be affected by her relationships with her friends and family. Her daughter's behavior problems in the home may be affected by the social and academic environment of her school. Assessment efforts cannot be confined to individual elements extracted from a complex array of interacting variables. Chaos theory and dynamic modeling also suggest that it may be difficult to develop powerful predictive or explanatory models unless we measure behavior within the complex dynamical systems in which the behavior is imbedded (Vallacher & Nowack, 1994)

4.07.3.1.8 Dynamic causal relationships

All elements of a functional analytic causal model—the causal variables that affect a client's behavior problems, the strengths of causal relationships, moderating variables, for example, are nonstationary (Haynes, Blaine, & Meyer, 1995). Causal relationships for a client can be expected to change across time in several ways. First, new causal variables may appear: Mr. or Mrs. A may develop new health problems; Mr. A may lose his job. Second, a causal variable may disappear: Mr. A may stop drinking; Mrs. A may give birth to her baby. Third, the strength and form of a causal relationship are likely to change over time. There may be a decrease in sleep disruption originally triggered by a traumatic event; marital distress that originally caused depressive symptoms may be exacerbated by continued depressive reactions. Fourth, moderating variables may change: Clients may change their expectancies about the beneficial effects of alcohol (Smith, 1994). In causal models of behavior disorders, a moderating variable is one that changes the relationship between two other variables. For example, "social support" would be a moderating variable if it affected the probability that an environmental disaster would be associated with symptoms of posttraumatic sress disorder (PTSD).

4.07.3.1.9 Additional assessment implications of causal assumptions

Emphases on multivariate, idiosyncratic, interactive, reciprocal deterministic, and dynamic causal models have several implications for behavioral assessment strategies that were briefly noted in the previous sections and will be discussed in greater detail later in this chapter. The assessment implications include: (i) pretreatment assessment should be broadly focused on multiple variables; (ii) classification will usually be insufficient to identify the causal variables operating for a particular client and insufficiently precise to identify the client's behavior problems; (iii) assessors should avoid "premature" or "biased" presumptions of causal relationships for a client and draw data-based inferences whenever possible; (iv) a valid functional analysis is most likely to result from assessment that focuses on multiple response modes, uses multiple methods; and gathers data from multiple sources; (v) it is important to identify the mechanisms underlying causal relationships (see also, discussion in Shadish, 1996); and (vi) a time-series assessment strategy can be an effective method of identifying and tracking behavior problems and potential causal factors.

4.07.3.2 Assumptions About the Characteristics of Behavior Problems

Behavioral assessment strategies and the resulting clinical case conceptualizations are strongly affected by assumptions of the behavioral assessment paradigm about the characteristics of behavior problems. Several of these assumptions were mentioned earlier in this chapter. They include the multimodal and multiparameter characteristics of behavior problems, differences among clients in the importance of behavior problem modes and parameters, the complex interrelationships among a client's multiple behavior problems, and the conditional and dynamic natures of behavior problems.

4.07.3.2.1 Behavior problems can have multiple response modes

Adult behavior problems can involve more than one response mode. For example, PTSD can involve physiological hyperreactivity, subjective distress, avoidance of trauma-related situations and thoughts, and distressing recollections and dreams of the traumatic event (American Psychiatric Association, 1994; Kubany, 1994). The degree of covariation among modes of a behavior problems can vary across persons (note that the *Diagnostic and statistical manual of mental disorders* [4th ed.] requires that a client manifest only one of five major [category B] symptoms for a diagnosis of PTSD). For example, some PTSD clients show only slight evidence of distressing recollections of the event but show significant physiological reactivity to event-related cues while others show the opposite pattern.

Low levels of covariation among the multiple modes of behavior problems have been found in both group nomothetic and single-subject time-series research (see discussion in Gannon & Haynes, 1987). Acknowledging that the apparent magnitude of covariation reflects the ways in which the modes are measured, these findings suggest that behavior problem modes can be discordant across persons and for one person across time. (See discussions in Cone (1979) and Eifert and Wilson (1991). Different response modes are often measured with different methods. Different response modes can also have different response latencies which can reduce apparent magnitudes of covariation if all modes are sampled simultaneously.)

Discordance among response modes for some clients has many clinical implications. Different response modes of a behavior problem may have different latencies in response to treatment. Furthermore, some treatments may have a stronger effect on some modes than on others. Consequently, the effects of treatment may be judged differently depending on which response mode is measured by which method. More important for a functional analysis of a patient, different response modes can be affected by different causal factors and respond differently to the same causal factor. Therefore, the selection of the most important mode for a client's behavior problem can affect the functional analysis and the intervention program designed for that client.

Assessment strategies should be congruent with the multimodal nature of behavior problems. First, because causal inferences are an important component of the functional analysis and guide treatment decisions, the primary mode of a client's behavior problem should be identified. Second, as the prior example of PTSD illustrated, diagnosis may be helpful but is usually an insufficient basis for the identification of the most important response modes for a client. Third, inferences regarding treatment effects for one mode may not be generalizable to other modes. In sum, behavioral assessment should have a multimodal focus.

4.07.3.2.2 Behavior problems have multiple parameters

As previously mentioned, each behavior problem mode can have multiple parameters. Parameters are quantitative dimensions, such as duration, magnitude, and rate, that can be used to describe a behavior. As with response modes, there are important between-client differences in the relative importance of different behavior problem parameters. For example, Mrs. A reported mildly intense but constant headaches and intermittent but severe sleep disruption. Other clients could report the same problems with different parameters (e.g., infrequent but debilitatingly intense headaches). Similarly, some clients report frequent but severe episodes of depression that last for only a few days; others report episodes of mild to moderate depression that can last months.

Multiple parameters of behavior disorders have important implications for the functional analysis because different parameters may be affected by different causal variables. For example, Barnett and Gotlib (1988) reviewed the literature on depression and suggested that learned helplessness beliefs seem to affect the duration and magnitude of depressive behaviors. However, learned helplessness beliefs could not account for the onset of depressive behaviors. Consequently, the functional analysis and treatment of a client with frequent depressive episodes might be different from the functional analysis and treatment of a client with infrequent but persistent depressive episodes.

One assessment implication that permeates many assumptions underlying behavioral assessment is that aggregated measures are insufficiently precise for a functional analysis. Between-person differences in the importance of behavior problem modes and parameters mandate careful specification and measurement of multiple modes and parameters. Measures of behavior problems that aggregate across modes, parameters, situations, for example, a single measure of "depression" or "anxiety," will often be insufficiently precise for the development of a functional analysis and for the design of intervention programs. Aggregated indices may be helpful as a general index of the magnitude or generality (or unconditional probability) of a behavior problem, but are insufficient for the precise inferences that are necessary for the evolution of assessment paradigms, functional analyses, and treatment strategies.

One helpful strategy for gathering more precise data on behavior problem parameters is the construction of a time-course for behavior problem—a time line reflecting occurrence, magnitude, and duration of behavior problems. An example of this method is the "timeline followback" by Sobell, Toneatto, and Sobell (1994) to establish a time-course of substance use.

4.07.3.2.3 Client can have multiple behavior problems

Many clients have multiple behavior problems. For example, Beck and Zebb (1994) reported that 65–88% of panic disorder patients have a coexisting behavior disorder, Figley (1979) reported a high incidence of comorbidity for PTSD, Regier et al., (1990) noted that drug users often have other concurrent behavior problems. Similar observations of comorbidity have been reported for panic disorders (Craske & Waikar, 1994) and depression (Persons & Fresco, 1996).

A client with multiple behavior problems challenges the clinical judgment capabilities of the assessor and complicates the functional analysis because the mode and parameter of each behavior problem can be affected by multiple causal variables: functional analytic causal models were developed partly as a method of organizing these clinical judgments. Additionally, multiple behavior problems can have complex causal and noncausal relationships. Note the relationships between sleep and headache problems for Mrs. A illustrated in Figure 1. Beach, Sandeen, and O'Leary (1990) observed a reciprocal causal relationship between marital distress depression for some patients (with many variables moderating that relationship). Hatch (1993) observed that depression can affect pain perception of headache patients and that headaches may contribute to the occurrence of depressive episodes for some patients.

The assumption that clients may have more than one behavior problem has several implications for behavioral assessment strategies. First, initial assessment, such as the intake interview (Kerns, 1994; Sarwer & Sayers, 1998) must be broadly focused to identify a client's multiple behavior problems. Premature narrowing of the assessment focus may preclude the identification of important behavior problems. Following a broad survey, subsequent assessment efforts can be focused on problem specification and the functional relationships relevant to each behavior problem. The functional analysis and intervention decisions will also be affected by estimates of the form and strength of relationship among, and relative importance of, a client's behavior problems. Multiple behavior problems also mandate a multivariate focus in treatment outcome evaluation.

Sometimes, the identification of functional response groups will aid in treatment decisions (Sprague & Horner, 1992). A functional response group is a set of behaviors, which may differ in form, that are under the control of the same contingencies (a set of behaviors that has the same function, (Haynes, 1996). Adaptive elements of the response class can sometimes be strengthened to weaken maladaptive elements of that class. Relaxation skills may be taught as a substitute for dysfunctional ways of reducing physiological hyperarousal. Effective communication skills may reduce the frequency of self-injurious behavior for some developmentally disabled individuals (Durand & Carr, 1991).

4.07.3.2.4 Behavior problems are conditional

As noted earlier in this chapter, behavior problems seldom occur randomly or unconditionally. Although it is difficult to predict the occurrence of many behavior problems, the probability of occurrence often varies as a function of settings, antecedent stimuli, environmental contexts, physiological states, and other discriminative stimuli (Gatchel, 1993; Glass, 1993; Ollendick & Hersen, 1993). It was previously noted that identifying sources of variance in behavior problems can help the assessor to identify causal variables and mechanisms. For example, behavioral assessors attempt to identify the conditions that trigger the startle responses of a client with PTSD (Foa, et al., 1989), that triggers a client's asthma episodes (Creer & Bender, 1993), and the conditions associated with marital violence (O'Leary, Vivian, & Malone, 1992) to develop a functional analysis and design the most appropriate intervention program.

The conditional nature of behavior problems further diminishes the clinical utility of aggregated measures of a behavior problem—assessment instruments that provide a "score" without providing more precise information of the conditional nature of the behavior problem. Assessment instruments should help the assessor examine the conditional probabilities of the behavior problem or the magnitude of shared variance between the behavior problem and multiple situational factors. For Mrs. A, the assessor would try to determine the situations that provoked conflict with her daughter, and to determine the events that increased or decreased the intensity of her headaches. Behavioral questionnaires and interviews, self-monitoring, and naturalistic observation can aid in identifying the conditional aspects of behavior problems.

4.07.3.2.5 The dynamic nature of behavior problems

The parameters and qualitative aspects (e.g., topography, form, characteristics) of behavior problems can change over time. The frequency, intensity, and content of arguments between Mr. and Mrs. A will probably change within a few weeks and months. The magnitude, frequency, duration, and form of a clients' PTSD symptoms, paranoid delusions, nightmares, excessive dieting, and pain can change in important ways across time. Also, new behavior problems may occur and some behavior problems may become less important.

Dynamic behavior problems and other variables can only be sensitively tracked by measuring them frequently, using time-series assessment strategies. The frequency with which dynamic variables should be sampled depends on their rate of change. Collins and Horn (1991), Heatherton and Weinberger (1994), Johnston and Pennypacker (1993), Kazdin (1997), and Kratochwill and Levin (1992) discuss instruments, strategies, and issues in the measurement of dynamic variables. Frequent measurement of behavior problems can also help the assessor identify important causal relationships. For example, recent changes in the magnitude of a client's depressive symptoms may provide cues about environmental or cognitive causal factors. Changes in Mrs. A's sleep patterns could trigger inquiries about events preceding the change. Self-monitoring, brief structured interviews and short questionnaires are particularly amenable to time-series assessment.

4.07.4 METHODOLOGICAL FOUNDATIONS OF BEHAVIORAL ASSESSMENT

The methodological elements of the behavioral assessment paradigm, the preferred strategies of behavioral assessment, are dictated by the assumptions about behavior and its causes outlined in the previous sections. Many of these methodological elements were introduced earlier in this chapter and are outlined in Table 1.

This section will discuss three of the elements of the behavioral assessment paradigm delineated in Table 1: (i) the emphasis on empirical hypothesis-testing, (ii) the idiographic emphasis, and (ii) the use of time-series assessment strategies. These and other methodological elements from Table 1 have been presented in Cone and Hawkins (1977), Haynes (1978), Hersen and Bellack (1996), Johnston and Pennypacker, (1993), Mash and Terdal (1988), Nelson and Hayes (1986), Ollendick and Hersen (1993), and Shapiro and Kratochwill (1988).

Most of the methodological elements of the behavioral assessment paradigm, particularly the assessment strategies, serve the priority placed on a scholarly, empirically based approach to clinical assessment. It is assumed that clinically useful knowledge about behavior problems is best acquired through the frequent administration of carefully constructed assessment instruments that are precisely focused of multiple, minimally inferential variables. Behavioral assessors are likely to eschew assessment instruments that are poorly validated, provide indices of vaguely defined and highly inferential constructs, and have unsubstantiated clinical utility.

4.07.4.1 An Empirically Based Hypothesis Testing Approach to Assessment

A hypothesis testing and refinement climate guides the behavioral assessment of adults. The assessor makes many tentative judgments about the client beginning early in the preintervention assessment phase. The clinician estimates the relative importance of the client's behavior problems and goals, the variables that influence problems and goals, and other elements of the functional analysis. Based on these early clinical judgments, the assessor also begins to estimate the most effective methods of intervention and selects additional assessment instruments, (see discussions in Eels, 1996; Haynes et al., 1997; Nezu et al., 1996; O'Brien & Haynes, 1995; Persons & Bertagnolli, 1994; Turk & Salovey, 1988). These hypotheses are tested and refined as assessment continues. With Mrs. A, for example, initial judgments that deficits in marital communications skills were functionally related to their marital conflicts would be evaluated subsequently through analogue communication assessment and by teaching the couple more positive discussion strategies. If their communication skills increased but their marital conflicts did not decrease invalid hypotheses may have been initially drawn about the causes of this couple's marital conflicts. There are other possible explanations for a lack of observed covariation in a causal relationship. For example, if another causal factor or moderating variable became operational while communication skills were strengthened, there could appear to be no causal relationship between communication skills and conflict (Shadish, 1996).

A scholarly hypotheses-testing approach to psychological assessment requires that the results of assessment and contingent clinical inferences be viewed skeptically. Clinical judgments are always based on imperfect measurements of nonstationary data and are intrinsically subjective. The validity and utility

Table 1 Methodological emphases of the behavioral assessment paradigm.

Assessment strategies

1. Idiographic assessment; a focus on the client's specific goals, individual behavior problems; individually tailored assessment; a de-emphasis on normatively based assessment (e.g., trait-focused questionnaires).
2. A hypothesis-testing approach to assessment and treatment (including the use of interrupted time-series designs).
3. Time-series assessment strategies (as opposed to single-point or pre–post measurement strategies); frequent measures of important variables.
4. Multimethod and multi-informant measurement of variables across multiple situations.
5. Quantification of variables (measurement of rates, magnitudes, durations).
6. The use of validated assessment instruments in conditions in which sources of measurement error are minimized.

The focus of assessment

7. Precisely specified, lower-level, and less inferential constructs and variables.
8. Observable behavior (as opposed to hypothesized intrapsychic events).
9. Client–environment interactions, sequences, chains, and reciprocal interactions.
10. Behavior in the natural environment.
11. Events that are temporally contiguous to behavior problems.
12. Multiple client and environmental variables in pretreatment assessment (multiple behavior problems, causal variables, moderating and mediating variables).
13. Multiple targets in treatment outcome evaluation (e.g., main treatment effects, side effects, setting and response generalization).
14. Multiple modes and parameters of behavior and other events.
15. Extended systems (e.g., family, work, economic variables).

Source: Haynes (1996b).
These are relative emphases whose importance varies across behavioral assessment subparadigms (e.g., behavior anlaysis, cognitive-behavioral). Many are compatible with other psychological assessment paradigms (e.g., neuropsychological, educational achievement).

of clinical judgments will covary with the degree to which they are guided by the assessment principles outlined in Table 1. The assessor can also reduce some of the biases in clinical judgments by basing them on assessment data and being receptive to clinical assessment data that is inconsistent with those judgments.

4.07.4.2 An Individualized Approach to Assessment

Partially due to between person differences in behavior problems, goals, and functional relationships, the behavioral assessment paradigm emphasizes individualized assessment—an idiographic approach to assessment (Cone, 1986). An individualized approach to assessment is manifested in several ways: (i) self-monitoring targets and sampling procedures are often tailored to the individual client; (ii) role play scenarios and other assessment instruments are often individually tailored (e.g., Chadwick, Lowe, Horne, & Higson, 1994); (iii) client-referenced and criterion-referenced assessment instruments, in contrast to norm-referenced assessment instruments, are often used; (iv) treatment goals and strategies are often individually tailored (e.g., de Beurs, Van Dyck, van Balkom, Lange, & Koele, 1994), and (v) within-subject, interrupted time-series and multivariate time-series designs are often used in research.

4.07.4.3 Time-series Assessment Strategies

As indicated in previous sections, time-series measurement of independent and dependent variables across time (e.g., the frequent [e.g., >40] daily samples of a client's behavior problems and causal variables) is an important strategy in behavioral assessment. It is a powerful strategy in clinical research and has many advantages in clinical assessment. First, it can help estimate causal and noncausal relationships for a participant's behavior problems. By subjecting the data to sequential analyses or cross-lagged correlations time-series assessment can provide information on conditional probabilities and suggest possible causal mechanisms for behavior problems (Bakeman & Gottman, 1986; Moran, Dumas, & Symons, 1992; Tryon, 1998).

A major advantage is that time-series assessment allows the researcher and clinician to control for and examine the temporal precedence of causal variables. As O'Leary, Malone, and Tyree (1994) noted in their discussion of marital violence, it is difficult to draw inferences about causal factors unless they are measured well ahead of the targeted behavior problem. A concurrent measurement strategy (in which hypothesized independent and dependent variables are measured concurrently) cannot be sufficient for causal inferences because the form (e.g., correlational, bidirectional causal) of the relationships cannot be established.

Statistical analysis of time-series data can be cumbersome in many clinical assessment contexts (however, see subsequent discussion of computer aids). However, time-series assessment is also the best strategy for tracking the time-course of behavior problems and goal attainment during therapy. Frequent monitoring increases the chance that failing treatment will be detected early (Mash & Hunsley, 1993) and that the clinician can make needed changes in the functional analysis and intervention programs.

Time-series assessment is congruent with an emphasis on professional accountability and empirically based judgments in clinical treatment. Time-course plots can be a useful means of documenting treatment effects and of providing feedback to clients about behavior change and possible causal relationships for their behavior problems. It can help the clinician identify naturally occurring causal mechanisms for a client's mood fluctuations, panic episodes, and other behavior problems. Time-series data was acquired with Mrs. A when she self-monitored daily her headaches and sleep problems.

Finally, time-series measurement is an essential element in interrupted time-series designs, such as the A–B–A–B, multiple baseline, or changing-criterion designs (Kazdin, 1997; Shapiro & Kratochwill, 1988). These designs can strengthen the internal validity of inferences about treatment effects and mechanisms.

4.07.4.4 Quantitative and Qualitative Approaches to Behavioral Assessment

The empirical elements of the behavioral assessment paradigm are partially responsible for the current emphasis on treatment outcome evaluation through frequently applied, minimally inferential, validated assessment instruments. This quantitative approach to clinical inference reflects and accentuates the growing importance of systematic evaluation by professionals delivering clinical services. The behavioral assessment paradigm provides a useful structure for the evaluation of clinical service delivery and intervention outcome. However, it is possible for clinicians and clinical researchers to overemphasize excessively molecular measures and excessive quantification. Quantification is an indispensable component of clinical inference but an exclusive reliance on quantification can promote a focus on variables and effects with minimal practical importance. The emphasis on clinical significance (e.g., Jacobson & Truax, 1991) of treatment effects and functional relationships reflects the practical and clinical importance of effects, as well as their statistical significance.

Qualitative analyses (Haberman, 1978) can compliment quantitative analyses. Behavioral assessors can generate clinically useful hypothesis by supplementing quantitative with qualitative analyses of clinical phenomena. Using time-sampling measurement strategies to code specific dyadic interaction sequences in a communication analogue between Mrs. and Mr. A provided data that helped identify dysfunctional verbal exchanges and provided the data base for judging the effects of communication training. However, it was also beneficial for the clinician to "passively" listen to the couple discuss their marital problems. Qualitative observation can be a rich source of ideas about the beliefs, attitudes, and behaviors that may contribute to marital distress.

Qualitative analyses can also promote the development of the behavioral assessment paradigm. We have only an elementary understanding of the causes of behavior disorders and of the best methods of treating them. An exclusive reliance on quantification can impair the evolution of any nascent assessment paradigm. Consequently, we must adopt a Steinbeckian attitude—generate and consider new ideas about functional relationships, presume that a new idea may be true, and then rigorously examine it.

Although I am advocating that qualitative methods can contribute to behavioral assessment, scientific methods remain the core element in the behavioral assessment paradigm. The stagnant nature of many psychological construct systems can be attributed to their focus on a rigidly invoked core set of assumptions about the nature of behavior and treatment, rather than on a core set of beliefs about the best way to learn about behavior and treatment. The behavioral assessment paradigm will continue to evolve to the degree that it emphasizes scientific methods for studying behavior, rather than a set of *a priori* beliefs about the nature of behavior disorders and their treatment.

4.07.5 BEHAVIORAL ASSESSMENT METHODS

There are many methods of behavioral assessment. Some, such as self-monitoring and behavioral observation, are congruent with and influenced by the conceptual and methodological elements of the behavioral assessment paradigm outlined earlier in this chapter. Others, such as trait-focused self-report questionnaires, are less congruent with the behavioral assessment paradigm. Surveys of journal publications and of the assessment methods used by practicing behavior therapists show that it is difficult to reliably categorize an assessment instrument as "behavioral" or "nonbehavioral"—categories of behavioral and nonbehavioral assessment methods are becoming increasingly indistinct. For example, many cognitive assessment instruments used by behavior therapists are aggregated and trait-based. They provide an unconditional "score" of some cognitive construct such as "self-efficacy beliefs" or "locus of control" (see discussion of cognitive assessment in Linscott & DiGiuseppe, 1998). Other assessment instruments and methods used by behavior therapists include neuropsychological assessment, sociometric status evaluation, the Minnesota Multiphasic Personality Inventory and other trait-based personality tests, aggregated mood scales, historically focused interviews, and tests of academic achievement (see Hersen & Bellack, 1998).

There are several bases for the decreasing distinction between behavioral and nonbehavioral assessment methods. First, many variables currently targeted in behavioral assessment (e.g., subjective distress, beliefs, mood) were not the focus of behavior therapy several decades ago. As the response modes in causal models of behavior disorders and the targets of behavioral treatments expanded beyond motor and verbal behavior, the array and focus of assessment instruments used in behavioral assessment expanded correspondingly.

Second, behavioral assessors are less predisposed to immediately reject all traditional self-report assessment instruments. Some well-validated "personality" assessment instruments can provide useful information. However, care should be taken to avoid unwarranted inferences from personality assessment instruments and to insure that, if used, they are part of an assessment program that includes more precisely focused assessment methods (see discussions of behavioral and personality assessment in *Behavior Modification*, 1993, No. 1, and general problems in personality assessment in Heatherton & Weinberger, 1994).

Third, in the 1960s and 1970s many behavior analysts denounced trait concepts and emphasized situational sources of behavior variance. The current person × situation interactional model of behavior variance, discussed earlier, suggests that clinical judgments can sometimes be aided by some trait measures, when used with situationally sensitive assessment instruments.

Fourth, the power of behavioral assessment methods often surpasses their clinical utility. Some behavioral assessment methods, such as behavioral observation, are costly and time-consuming, which decreases their usefulness in clinical assessment (however, as discussed in subsequent sections, many technological advances have enhanced the clinical utility of some behavioral assessment methods).

Finally, behavioral assessors are sometimes insufficiently educated in psychometric principles and in the degree to which assessment strategies match the conceptual and methodological aspects of the behavioral assessment paradigm. For example, behavioral assessors sometimes use an aggregated score from an assessment instrument that has multiple uncorrelated factors. At other times an aggregated score is used when there is important between-situation variance in the measured construct. Also, norm-referenced assessment instruments are sometimes applied when they are not psychometrically appropriate or useful with a particular client (norms may not be available for the client's ethnic group, age, or economic status; Cone, 1996; Haynes & Wai'alae, 1995; Silva, 1993).

The following sections briefly present four categories of behavioral assessment methods: (i) behavioral observation, in the natural environment and in analogue situations; (ii) self-monitoring; (iii) self-report interviews and questionnaires; and (iv) psychophysiological assessment. The specific strategies, conceptual foundations, utility, psychometric properties, disadvantages, technical advancements, and contribution to clinical judgment of each category will be discussed. Coverage of these methods is necessarily limited and more extensive presentations of behavioral assessment methods and instruments can be found in books by Hersen and Bellack (1998), Mash and Terdal (1988), Ollendick and Hersen (1993), and Shapiro and Kratochwil (1988).

4.07.5.1 Behavioral Observation

Behavioral observation involves the time-series observation of molecular, precisely defined behaviors, and environmental events. Usually, an observation session is divided into smaller time samples and the occurrence of discrete events within each time sample is recorded by external observers (Foster & Cone, 1986; Foster, Bell-Dolan, & Burge, 1988; Mash & Hunsley, 1990; Tryon, 1998).

Two observation strategies, and variants of each, are discussed below: behavioral observation in the natural environment and behavioral observation in analogue environments.

4.07.5.1.1 Behavioral observation in the natural environment

Systematic behavioral observation of clients is congruent with most of the underlying assumptions of the behavioral assessment paradigm. Quantitative, minimally inferential data are derived on clients in their natural environment using external observers (nonparticipant observers). Behavior observation systems can be constructed for individual patients, some sources of measurement error can be examined through interrater reliability coefficients, and the acquired data can provide valuable information for the functional analysis and for treatment outcome evaluation. Observation in the natural environments has been used in the assessment of self-injurious, delusional, and hallucinatory behaviors in institutions; eating and drinking in restaurants, bars, and in the home; marital and family interactions in the home; student, teacher, and peer interactions in schools; pain and other health-related behaviors at home and in medical centers; community-related behaviors (e.g., driving, littering); and many other behaviors.

Typically, the client is observed for brief periods (e.g., one hour) in his or her natural environment (e.g., at home) several times in "sensitive" or "high-risk" situations—situations or times with an elevated probability that important behaviors or interactions will occur (e.g., at dinnertime when observing problematic family interactions; at mealtime when observing the social interactions of a psychiatric inpatient). Trained observers record the occurrence/nonoccurrence of specified and carefully defined behaviors within *time-sampling* periods (e.g., 15-second periods). Sequences of events (e.g., sequential interactions between a depressed client and family members) and the duration of events can also be recorded. Observers can also use momentary time sampling and record the behaviors that are occurring at predetermined time sampling points. An example of this latter sampling strategy would be a nurse recording the social interactions of a psychiatric inpatient at the beginning of every hour.

Observation in unrestricted environments (e.g., in a client's home) can be problematic because clients are sometimes out of sight of the observers and sometimes engage in behaviors that are incompatible with the purposes of the observation (e.g., talking on the phone; watching TV). Consequently, the behavior of the individual to be observed is often constrained. For example, a marital couple being observed at home might be requested to remain within sight of the observer, to avoid long phone conversations, and keep the TV off. Such constraints compromise the generalizability of the obtained data but increase the efficiency of the observation process.

The temporal parameters (the length, frequency, spacing, and sampling intervals) of an observation session are influenced by the characteristics of the targeted behaviors. For example, higher rate behaviors require shorter time sampling intervals. Highly variable behaviors required more observation sessions. Suen and Ary (1989) discuss temporal parameters of behavioral observation in more detail.

Behavioral observation in the natural environment has many applications. It is a powerful method of treatment outcome evaluation because it minimizes many sources of measurement error associated with self-report and is sensitive to behavior change. It has also been used as a basic research tool in the behavioral and social sciences and to gather data for functional analyses.

The clinical utility of behavioral observation in the natural environment is limited in several ways. It is not cost-efficient for the assessment of very low frequency behaviors, such as stealing, seizures, and some aggressive behaviors. Also, "internalized," covert behavior problems such as mood disorders and anxiety are less amenable to external observation (although some verbal and motoric components of these disorders can be observed). Socially sensitive or high-valence behaviors, such as sexual dysfunctions, paraphiliac behaviors, substance use, and marital violence may not be emitted in the presence of observers. In most outpatient clinical settings, observation in the natural environment with external observers is prohibitively expensive and time-consuming.

Behavioral observation is an expensive assessment method but technological advances have enhanced its clinical utility. Audio and video tape recorders and other instrumentation can facilitate the acquisition of observation data on clients in the natural environment without having to send observers (Tryon, 1991). Observers can also use hand-held computers to record and analyze observation data in real-time (Tryon, 1998).

Because many behaviors can be observed, behavior sampling is an indispensable component of behavioral observation. Typically, observers use a standardized behavior coding system (e.g., Marital Interaction Coding System; Weiss & Summers, 1983) that contains preselected behavior codes. Behaviors selected for inclusion in behavioral observation include: (i) client problem behaviors (e.g., social initiation behaviors by a depressed psychiatric inpatient), (ii) causal variables for the client's behavior problems and goals (e.g., compliments and insults emitted during distressed marital interaction), (iii) behaviors correlated with client problem behaviors (e.g., members of a functional response class such as verbal and physical aggressive behaviors), (iv) salient, important, high-risk behaviors (e.g., suicide talk), (v) client goals and positive alternatives to undesirable behaviors (e.g., positive social interactions by a delusional or socially isolated client), (vi) anticipated immediate, intermediate, and final outcomes of treatment, and (vii) possible positive and negative side- and generalized effects of treatment.

Although observers sometimes focus on only one individual, it is more common in behavioral observation to monitor interpersonal interactions. To this end, observers can record sequences of interactions between two or more individuals (see discussions in Bakeman & Gottman, 1986; Moran et al., 1992). When the goal of observation is to draw inferences about a group of persons, subject sampling can be used. A few persons may be selected for observation from a larger group. For example, several patients may be selected for observation if the goal is to document the effects of a new token program on patients in a psychiatric unit.

Behavioral observation is often considered the "gold standard" for assessment. However, there are several sources of error which can detract from the accuracy and validity of obtained data and of the inferences drawn from them. Sources of error in behavioral observation include: (i) the degree to which observers are trained, (ii) the composition and rotation of observer teams, (iii) observer bias and drift, (iv) the behaviors selected for observation, (v) the specificity of code definitions, (vi) the methods of evaluating interobserver agreement, (vii) the match between time samples and the dynamic characteristics of the observed behaviors, (viii) variance in the situations or time of day in which observation occurs (Alessi, 1988; Hartmann, 1982; Suen & Ary, 1989; Tryon, 1996).

Several types of data can be derived from behavioral observation. Often, assessors are interested in the rate of targeted events. This is usually calculated as the percent of sampling intervals in which a behavior occurs. Sequential analyses and conditional probabilities are often more important for developing functional analyses. For example, observation of family interaction in the home can provide data on negative reciprocity—the relative probability that one family member will respond negatively following a negative (in comparison to a nonnegative) response by another family member. Particularly with computer-aided observation, data on the duration of behaviors can also be acquired. Some observation systems use ratings by observers, rather than event recordings, although these are more frequently conducted outside formal observation session (Segal & Fal, 1998; Spector, 1992). According to McReynolds (1986), the first rating scale was published by Thomasius in 1692. Four basic characterological dimensions were rated—sensuousness, acquisiteveness, social ambition, and rational love.

"Reactivity" refers to the degree to which asessment modifies the targets of assessment. Reactivity is a potential source of inferential error in all assessment procedures, but particularly in behavioral observation (Foster et al., 1988; Haynes & Horn, 1982). The behavior of clients, psychiatric staff members, spouses, and parents may change as a function of whether observers are present or absent. Therefore, reactivity threatens the external validity or situational and temporal generalizability of the acquired data. In the cases of some highly socially sensitive behaviors (e.g., sexual or antisocial behaviors), the magnitude of reactivity may be sufficient to preclude observation in the natural environment.

Participant observation is an alternative to the use of nonparticipant observers. Participant observation is behavioral observation, as described above, using observers who are normally part of the client's natural environment. (In ethnography and cultural anthropology, the term "participant observation" usually refers to qualitative observation by external observers who immerse themselves in the social system they are observing.) Examples of participant observation include: (i) parents observing the play behavior of their children, (ii) nurses observing the delusional speech of psychiatric inpatients, and (iv) a spouse observing a client's depressive or seizure behaviors. Participant observers often use time and behavior sampling procedures similar to those used by nonparticipant observers. However, participant observers are usually less well trained and apply less complex observation systems (e.g., fewer codes, use of momentary time sampling). For example, a staff member on a psychiatric unit might monitor the frequency of social initiations by a client only during short mealtime periods or only briefly throughout the day.

The primary advantages of participant observation are its cost-efficiency and applicability. Participant observation can be an inexpensive method of gathering data on clients in their natural environment. It may be particularly advantageous for gathering data on low frequency behaviors and on behaviors that are highly reactive to the presence of external observers.

There are several potential sources of error in participant observation. First, it is susceptible to most of the sources of error mentioned for nonparticipant observation (e.g., behavior definitions, time sampling errors). Additionally, participant observation may be particularly sensitive to observer biases, selective attention by observers, and recent interactions with the target of observation. The observer is likely to be less well trained and often is not a neutral figure in the social context of the client.

Participant observation may be associated with reactive effects. Sometimes, the reactive effects would be expected to be less for participant than for nonparticipant observation. One determining factor in reactivity is the degree to which the assessment process modifies the natural environment of the client. Because participant observation involves less change in the natural environment of the client, it may be less reactive. However, the reactive effects of participant observation may be strengthened, depending on the method of recording, the behaviors recorded, and the relationship between the observer and client. In some situations participant observation might be expected to alter the monitored behavior to an important degree or to adversely affect the relationship between the observer and target (e.g., an individual monitoring the sexual or eating behavior of a spouse).

Critical event sampling is another infrequently used but clinically useful and cost-efficient method of acquiring natural environment observation data. Critical event sampling involves video or audio tape recording of important interactions in the client's natural environment (Jacob, Tennenbaurm, Bargiel, & Seilhamer, 1995; Tryon, 1998). The critical interactions are later qualitatively or quantitatively analyzed. For example, a tape recorder could be self-actuated by a distressed family during mealtime; a marital couple could record their verbal alterations at home; a socially anxious individual could record conversations while on a date.

4.07.5.1.2 Analogue observation

Analogue observation involves the systematic behavioral observation of clients in carefully structured environments. The assessment environment is arranged to increase the probability that clinically important behaviors and functional relationships can be observed. It is a powerful, clinically useful, and idiographic behavioral assessment method. Many elements of the analogue assessment setting are similar to those of the client's natural environment. However, the participants, social and physical stimuli, and instructions to the client may differ from those of the client's natural environment.

The behavior of clients in analogue assessment is presumed to correlate with their behavior in the natural environment. For example, a distressed marital couple might discuss a problem in their relationship while in a clinic and being observed from a one-way mirror. It is presumed that the problem-solving strategies they use will be similar to those they use outside the clinic.

Analogue observation has many applications. The role play is often used in the behavioral assessment of social skills. A psychiatric patient or socially anxious adult might be observed in a clinic waiting room while attempting to initiate and maintain a conversation with a confederate. A client might be placed in a simulated social situation (e.g., simulated restaurant) and asked to respond to social stimuli provided by a confederate. The Behaviour Avoidance Test (BAT; e.g., Beck & Zebb, 1994) is another form of analogue observation. In a BAT, a client is prompted to approach an object that is feared or avoided.

Analogue methods have been used in the assessment of many clinical phenomena, such as pain (Edens & Gil, 1995), articulated thoughts (Davison, Navarre, & Vogel, 1995), and social anxiety and phobia (Newman, Hofmann, Trabert, Roth, & Taylor, 1994). Other applications include the study of self-injurious behaviors, dental anxiety, stuttering, heterosexual anxiety, alcohol ingestion, panic episodes, cigarette refusal skills, parent–child interaction, speech anxiety, animal phobias, test anxiety, and eating patterns.

Data can be acquired on multiple response modes in analogue observation. For example, during exposure to an anxiety provoking social exchange, clients can report their level of anxiety and discomfort, electrophysiological measures can be taken, observers can record the behavior of the client, and clients can report their thoughts.

Analogue observation is a cost-efficient and multimodal method of assessment and can be a useful supplement to retrospective interview and questionnaire methods. It provides a means of directly observing the client in sensitive situations and of obtaining *in vivo* client reports to supplement the client's retrospective report of thoughts, emotions, and behavior. In comparison to observation in the natural environment, it is particularly useful for observing some important but low-rate events (e.g., marital arguments).

When used in conjunction with systematic manipulation of hypothesized controlling variables analogue observation can be exceptionally useful for identifying causal relationships and for constructing a functional analysis of behavior problems. For example, social attention, tangible rewards, and task demands can be systematically presented and withdrawn before and after the self-injurious behavior of developmentally disabled individuals (e.g., Iwata et al., 1994). Systematic manipulation of hypothesized controlling factors during analogue observation has also been used to identify the cognitive sequelae of hyperventilation during anxiety episodes (Schmidt & Telch, 1994), the most effective reinforcers to use in therapy (Timberlake & Farmer-Dougan, 1991), and the factors associated with food refusal (Munk & Repp, 1994).

Analogue observation is associated with several unique sources of variance, measurement error, and inferential error (e.g., Hughes & Haynes, 1978; Kern, 1991; Torgrud & Holborn, 1992). First, because the physical environment and social stimuli are more carefully controlled in analogue observation but may differ from those in the client's naturalistic environment, external validity may be reduced concomitantly with an increase in behavioral stability. The behavior of clients and the data acquired during analogue observation can covary with: (i) the physical characteristics of the assessment environment; (ii) the instructions to participants; (iii) observer and sampling errors, such as those outlined in naturalistic observation, time and behavior sampling; and (iv) the content validity of the assessment environment (i.e., the degree to which the stimuli are relevant to the construct being measured by the analogue assessment situation).

The primary disadvantage to analogue observation is its representational nature: the data acquired in analogue assessment are only presumed to correlate with data that would be acquired in the natural situations the analogue assessment is designed to represent. It is an indirect measure of the individual's behavior in the natural environment. The results of many studies have supported the discriminant and criterion-related validity of analogue observation; the results of other validation studies have suggested more cautious conclusions. Given the presumption that many behaviors are sensitive to situational sources of variance, clients can be expected to behave differently in analogue and natural environments. That is, the behavior of clients in analogue settings may not accurately reflect or match their behavior in the natural environment. Nevertheless, analogue assessment should be expected to be valid in other ways. For example, socially anxious and nonanxious clients should behave differently during analogue observation even if their behaviors do not match their behaviors in the natural environment. The validity and clinical utility of analogue observation should be considered dependent variables. They are likely to vary across the purposes of the assessment, subjects, target behaviors, settings, and observation methods.

4.07.5.2 Self-monitoring

In self-monitoring, clients systematically record their behavior and sometimes relevant environmental events (Bornstein, Hamilton, & Bornstein, 1986; Gardner & Cole, 1988; Shapiro, 1984). The events to be recorded by the client are first identified and specified by the client and assessor during an interview. A recording form is developed or selected and the client monitors the designated events, sometimes at designated times or in specified situations. To reduce errors associated with retrospective reports, recording usually occurs immediately before or after the monitored event.

One particularly innovative development is self-monitoring via hand-held computer and computer-assisted data acquisition and analysis (Agras, Taylor, Feldman, Losch, & Burnett, 1990; Shiffman, 1993). Hand-held computers allow the collection of real-time data and simplify the analysis and presentation of self-monitoring data. Computerization should significantly increase the clinical utility of self-monitoring.

Time-sampling is sometimes used with self-monitoring, depending on the characteristics of the behavior. Clients can easily record every occurrence of very low-rate behaviors such as seizures or migraine headaches. However, with high-rate or continuous behaviors, such negative thoughts, blood pressure, and mood, clients recordings may be restricted to specified time periods or situations.

Many clinically important behaviors have been the targets of self-monitoring. These include ingestive behaviors (e.g., eating, caffeine intake, alcohol and drug intake, smoking), specific thoughts (e.g., self-criticisms); physiological phenomena and medical problems (e.g., bruxism, blood pressure, nausea associated with chemotherapy, Raynaud's symptoms, arthritic and other chronic pain, heart rate, seizures); and a variety of other phenomena such as self-injurious behaviors, electricity use, startle responses, sexual behavior, self-care behaviors, exercise, panic and asthma episodes, social anxiety, mood, marital interactions, study time, sleeping patterns, and nightmares.

Many response modes are amenable to measurement with self-monitoring. Clients can monitor overt motor behavior, verbal behavior, subjective distress and mood, emotional responses, occurrence of environmental events associated with their behavior, physiological responses, thoughts, and the qualitative characteristics of their behavior problems (e.g., location of headaches, specific negative thoughts, multimodal aspects of panic episodes). Self-monitoring can also be used to track multiple response parameters: response durations, magnitudes, and frequencies. Of particular relevance for the functional analysis, the client can concurrently monitor behaviors, antecedent events, and consequent events to help identify functional relationships. Johnson, Schlundt, Barclay, Carr-Nangle, and Engler (1995), for example, had eating disordered clients monitor the occurrence of binge eating episodes and the social situations in which they occurred in order to calculate conditional probabilities for binge eating.

Self-monitoring is a clinically useful assessment method. Self-monitoring can be tailored for individual clients and used with a range of behavior problems. It is an efficient and inexpensive assessment method for gathering data on functional relationships in the natural environment and is another important supplement to retrospective self-report. It is suitable for time-series assessment and for the derivation of quantitative indices of multiple response modes. Self-monitoring is applicable with many populations—adult outpatients, children, inpatients, parents and teachers, and developmental disabled individuals. Events that, because of their frequency or reactive effects, are not amenable to observation by participant and nonparticipant observers may be more amenable to assessment with self-monitoring.

Although many validation studies on self-monitoring have been supportive (see reviews in Bornstein et al., 1986; Gardner & Cole, 1988; Shapiro, 1984) there are several threats to the validity of this assessment method. Two important sources of error in self-monitoring are clients' recording errors and biases. The resultant data can reflect the client's abilities to track and record behaviors, client expectancies, selective attention, missed recording periods, the social valence and importance of the target behaviors, fabrication, and the contingencies associated with the acquired data. Data can also be affected by how well the client was trained in self-monitoring procedures, the demands of the self-monitoring task, the degree to which target events have been clearly specified, reactions from family and friends to the client's monitoring, and the frequency and duration of the targeted behaviors. Clinical researchers have also reported difficulty securing cooperation from clients to self-monitor for extended periods of time. One particularly powerful source of inferential error is reactivity (Bornstein et al., 1986). The reactive effects of self-monitoring are frequently so great that self-monitoring is sometimes used as a method of treatment.

4.07.5.3 Psychophysiological Assessment

Psychophysiological measurement is an increasingly important method in behavioral assessment (Haynes, Falkin, & Sexton-Radek, 1989). The increased emphasis on psychophysiological assessment is due, in part, to a growing recognition of the importance of physiological components of behavior problems, such as depression, anxiety, and many psychotic behavior problems. Also, behavior therapists are increasingly involved in the assessment and treatment of disorders that have traditionally been the focus of medical interventions—cancer, chronic pain, diabetes, cardiovascular disorders. A third reason for the importance of psychophysiological assessment is that many behavioral intervention procedures, such as relaxation training and desensitization, focus partly on the modification of physiological processes. Advances in ambulatory monitoring, computerization, and other technologies have increased the clinical utility of psychophysiological measurement. Finally, psychophysiological measurement can easily be combined with other behavioral assessment methods, such as self-monitoring and analogue observation.

The recognition of the importance of the physiological response mode in behavior problems mandates the inclusion of electrophysiological and other psychophysiological measurement methods. Electromyographic, electrocardiovascular, electroencephalographic, and electrodermal measures are particularly applicable to behavioral assessment with adults. A range of behavior problems (e.g., panic disorders, PTSD, schizophrenic behaviors, obsessive-compulsive behaviors, worry, depression, substance abuse, disorders of initiating and maintaining sleep) have important physiological components. The low magnitude of covariance between physiological and other response modes, noted earlier in this chapter, suggests that they may be a function of different causal variables and respond differently to the same treatment.

Psychophysiological measurement is a complex, powerful, and clinically useful assessment method in many assessment contexts and for many clients. It is amenable to idiographic assessment, can be applied in a time-series format, and generates quantitative indices. The validity of the obtained measures can be affected by electrode placement, site resistance, movement, instructional variables, time-sampling parameters, data reduction and analysis, equipment intrusiveness, and equipment failures. Books by Andreassi (1995) and Cacioppo and Tassinary (1990) cover instrumentation, measurement methods, technological innovations, clinical applications, and sources of measurement error.

4.07.5.4 Self-report Methods in Behavioral Assessment

Many interview formats and hundreds of self-report questionnaires have been adopted by behavioral assessors from other assessment paradigms. A comprehensive presentation of these methods is not possible within the confines of this chapter. Here, I will emphasize how behavioral and traditional self-report methods differ in format and content. The differences reflect the contrasting assumptions of behavioral and nonbehavioral assessment paradigms.

More extensive discussions of self-report questionnaire and interview methods, and applicable psychometric principles are provided by Anastasi (1988), Jensen and Haynes (1986), Nunnally and Bernstein (1994), Sarwer and Sayers (1998), and Turkat (1986)

Behavioral assessors, particularly those affiliated with an applied behavior analysis paradigm, have traditionally viewed self-report questionnaires and interviews with skepticism. Objections have focused on the content and misuses of these methods. Many questionnaires solicit retrospective reports, stress situationally insensitive aggregated indices of traits, focus on molar level constructs that lack consensual validity, and are unsuited for idiographic assessment. Biased recall, demand factors, item interpretation errors, and memory lapses, further challenged the utility of self-report questionnaires. Data from interviews have been subject to the same sources of error with additional error variance associated with the behavior and characteristics of the interviewer. Despite these constraints, interviews and questionnaires are the most frequently used methods used by behavior therapists (e.g., Piotrowski & Zalewski, 1993).

The interview is an indispensable part of behavioral assessment and treatment and undoubtedly is the most frequently used assessment method. All behavioral interventions require prior verbal interaction with the client or significant individuals (e.g., staff) and the structure and content of that interview can have an important impact on subsequent assessment and treatment activities.

As illustrated with Mrs. A, an assessment interview can be used for multiple purposes. First, it can help identify and rank order the client's behavior problems and goals. It can also be a source of information on the client's reciprocal interactions with other people, and, consequently, provides important data for the functional analysis. Interviews are the main vehicles for informed consent for assessment and therapy and can help establish a positive relationship between the behavior assessor and client. Additionally, interviews are used to select clients for therapy, to determine overall assessment strategies, to gather historical information, and to develop preliminary hypotheses about functional relationships relevant to the client's behavior problems and goals.

The behavioral assessment interview differs from nonbehavioral interviews in content and format. First, the behavioral interview is often more quantitatively oriented and structured (although most behavioral interviews involve unstructured, nondirective, and client-centered phases). The focus of the behavioral interview reflects assumptions of the behavioral assessment paradigm about behavior problems and causal variables and emphasizes current rather than historical behaviors and determinants. Behavioral interviewers are more likely to query about situational sources of behavioral variance and to seek specification of molecular behaviors and events.

A systems perspective also guides the behavioral assessment interview. The behavioral interviewer queries about the client's extended social network and the social and work environment of care-givers (e.g., the incentives at a psychiatric institution that encourage cooperation by staff members). The interviewer also evaluates the effects that treatment may have on the client's social system—will treatment effect family or work interactions?

Some of the concerns with the interview as a source of assessment information reside with its traditionally unstructured applications. Under unstructured conditions, data derived from the interview may covary significantly with the behavior and biases of the interviewer. However, structured interviews and technological advances in interview methods promise to reduce such sources of error (Hersen & Turner, 1994; Sarwer & Sayers, 1998). Computerization, to guide the interviewer and as an interactive system with clients, promises to reduce some sources of error in the interview process. Computerization can also increase the efficiency of the interview and assist in the summarization and integration of interview-derived data.

Other structured interview aids, such as the Timeline Followback (Sobell, Toneatto, & Sobell, 1994) may also increase the accuracy of the data derived in interviews. In Timeline Followback, memory aids are used to enhance accuracy of retrospective recall of substance use. A calendar is used as a visual aid, with the client noting key dates, long periods in which they abstained or were continuously drunk, and other discreet events associated with substance use.

Some interviews are oriented to the information required for a functional analysis. For example, the Motivation Assessment Scale is used with care-givers to ascertain the factors that may be maintaining or triggering self-injurious behavior in developmentally disabled persons (Durand & Crimmins, 1988).

Questionnaires, including rating scales, self-report questionnaires, and problem inventories, are also frequently used in behavioral assessment; they have probably been frequently used with all adult behavior disorders. Many questionnaires used by behavioral assessors are identical to those used in traditional nonbehavioral psychological assessment. As noted earlier, questionnaires are often adopted by behavioral assessors without sufficient thought to their underlying assumptions about behavior and the causes of behavior problems, content validity, psychometric properties, and incremental clinical utility. They are often trait-focused, insensitive to the conditional nature of the targeted behavior, and provide aggregated indices of a multifaceted behavioral construct (Haynes & Uchigakiuchi, 1993). Questionnaires are sometimes helpful for initial screening or as a nonspecific index of program outcome but are not useful for a functional analysis or for precise evaluation of treatment effects. The integration of personality and assessment is addressed further in a subsequent section of this chapter.

Some questionnaires are more congruent with the behavioral assessment paradigm. These usually target a narrower range of adult behavior problems or events, such as panic and anxiety symptoms, outcome expectancies for alcohol, recent life stressors, and tactics for resolving interpersonal conflicts. Most behaviorally oriented questionnaires focus on specific and lower-level behaviors and events and query about situational factors. However, the developers of behaviorally oriented questionnaires sometimes rely on the face validity of questionnaires and do not follow standard psychometric principles of questionnaire development (see special issue on "Methodological issues in psychological assessment research" in *Psychological Assessment*, 1995, Vol. 7). Deficiencies in the development and validation of any assessment instrument reduce confidence in the inferences that can be drawn from resulting scores.

Questionnaires, given appropriate construction and validation, can be an efficient and useful source of behavioral assessment data. Most are inexpensive, quick to administer and score, and are well received by clients. Computer administration and scoring can increase their efficiency and remove several sources of error (Honaker & Fowler, 1990). They can be designed to yield data on functional relationships of variables at a clinically useful level of specificity.

4.07.5.5 Psychometric Foundations of Behavioral Assessment

The application of psychometric principles to behavioral assessment instruments has been discussed in many books and articles (e.g., Cone, 1988; 1996; Foster & Cone, 1995; Haynes & Wai'alae, 1995; Silva, 1993; see also "Methodological issues in psychological assessment research," *Psychological Assessment*, September, 1995). Psychometric principles were originally applied to tests of academic achievement, intelligence, and abilities. Because many of the principles were based on estimating measurement error with presumably stable and molar-level phenomena, the relevance of psychometric principles to behavioral assessment has been questioned. However, "psychometry" is best viewed as a general validation process that is applicable to any method or instrument of psychological assessment.

The ultimate interest of psychometry is the construct validity of an assessment instrument or, more precisely, the construct validity of the data and inferences derived from an assessment instrument. Construct validity is comprised of the multiple lines of evidence and rationales supporting the trustworthiness of assessment instrument data interpretation (Messick, 1993). Indices of construct validity are also conditional—an index of validity does not reside unconditionally with the instrument (Silverman & Kurtines, 1998, discuss contextual issues in assessment). Elements of construct validation are differentially applicable, depending on the method, target, and purpose of assessment.

The validity of data derived from an assessment instrument establishes the upper limit of confidence in the clinical judgments to which the instrument contributes. Consequently, the validity of every element of the functional analysis is contingent on the validity of the assessment instruments used to collect contributing data. The validity of other clinical judgments (e.g., risk factors for relapse, and the degree of treatment effectiveness) similarly depends on the validity of assessment data.

The applicability of psychometric principles (e.g., internal consistency, temporal stability, content validity, criterion-related validity) to behavioral assessment instruments varies with their methods, targets, and applications. The data obtained in behavioral assessment differ in the degree to which they are presumed to measure lower-level less-inferential variables (e.g., number of interruptions in a conversation, hitting) or higher-level more inferential variables (e.g., positive communication strategies, aggression). With lower-level variables, psychometric indices such as internal consistency and factor structure are not useful indications of validity of the obtained data. Interobserver agreement and content validity may be more useful indices.

The validity of data from an assessment instrument depends on how it will be used—on the clinical judgments that it affects. For example, accurate data may be obtained from analogue observation of clients social interactions. That is, there may be perfect agreement among multiple observers about the client's rate of eye contact, questions, and reflections. However, those rates may demonstrate low levels of covariance (i.e., low criterion-referenced validity) with the same behaviors measured in natural settings. The relative importance of accuracy and other forms of validity varies with the purpose of the assessment (see Cone, 1998). If the analogue data is used to evaluate the effectiveness of a social skills training program, accuracy is an important consideration. If the data is to be used to evaluate generalization of treatment effects, accuracy is necessary but not sufficient.

The interpretation of temporal and situational stability coefficients is complicated in behavioral assessment by the conditional and unstable nature of some of the targeted phenomena (e.g., appetitive disorders, social behaviors, mood, expectancies). Indices of instability (e.g., low test–retest correlations) can reflect variability due to true change across time in the variable (e.g., change in the social behavior of an observed client) as well as measurement error (e.g., poorly defined behavior codes, observer error). Consequently, temporal stability coefficients, by themselves are weak indices of validity. A multimethod/multi-instrument assessment strategy, by providing indices of covariance among measures of the same targeted phenomena, however, can help separate true from error variance. Additionally, a low magnitude of temporal stability in a time-series measurement strategy has implications for the number of samples necessary to estimate or capture the time course of the measured phenomena—unstable phenomena require more sampling periods than do stable phenomena.

Behavioral assessment often involves multiple methods of assessment, focused on multiple modes and parameters. As noted earlier in this chapter, sources of measurement error and determinants can vary across methods, modes, and parameters. A multimethod approach to assessment can strengthen confidence in subsequent clinical judgments. However, estimates of covariance are often used as indices of validity and can be attenuated in comparison to monomethod or monomode assessment strategies (see discussion of psychometric indices of multiple methods in Rychtarik & McGillicuddy, 1996).

The individualized nature of behavioral assessment enhances the importance of some construct validity elements. For example, accuracy, content validity, and interobserver agreement are important considerations in behavioral observation coding systems. Idiographic assessment reduces the importance of construct validity elements such as nomothetically based discriminant and convergent validity.

4.07.6 BEHAVIORAL AND PERSONALITY ASSESSMENT

As noted earlier in this chapter, behavioral assessors often use traditional personality questionnaires and several possible reasons for this integration were given. The positive cost-efficiency of personality trait measures is one factor. One of the more empirically based rationales for integration is a person × situation interactional model for assessment: if we want to predict a person's behavior, it helps to know something about the relatively stable aspects of the person and something about the situations that promote instability, at least sometimes (McFall & McDonel, 1986). Personality questionnaires are often used in initial screening, followed by more specifically focused, molecular, and less inferential assessment instruments. Noted in this section are several additional issues concerning the integration of personality and behavioral assessment. These issues were discussed in Haynes and Uchigakiuchi (1993) and in other articles in a special section of *Behavior Modification*, 1993, *17*(1).

There are several complications associated with adopting the situation × person interaction model and with the use of personality assessment instruments. Given that there are hundreds of traits measurable by extant instruments, it is difficult to determine which traits to measure, and how best to measure them. Also, despite a growing literature on situational factors in behavior disorders, we still do not know which aspects of situations can be most important in controlling behavioral variance for a particular client (e.g., Kazdin, 1979). Nor do we know under which conditions a person–situation interaction model, as opposed to a situational or trait model, will assume the greatest predictive efficacy.

Several additional issues regarding the trait × situation interactional model of behavior and the utility of personality assessment strategies for behavioral assessment have already been discussed in this chapter and in many previously published articles. First, personality traits vary in theoretical connotations and the theoretical connotations of a trait measure influence its utility for behavioral assessment. Many constructs measures by personality assessment instruments have psychodynamic and intrinsically causal connotations. Some, such as "emotional instability," "hardiness," and "passive–aggressive," refer to an internal state that is presumed to control observed behavior—these traits invoke causal models that are inconsistent with aspects of the behavioral assessment paradigm. In these cases "psychological processes" are inferred from cross-situational consistencies in behavior. In a circular fashion, the processes become explanations for the behaviors that are their indicators. The processes cannot be independently validated, are difficult to measure, and the inferential process can inhibit a scientific investigation of these behaviors.

Personality questionnaires invariable invoke molar-level traits whose interpretation require normative comparison. Consequently, trait measures are less amenable to idiographic assessment of lower-level variables. Clinical inferences about a person on a trait dimension are derived by comparing the person's aggregated trait score to the trait scores of a large sample of persons. Such comparative inferences can be helpful but can also be in error if there are important differences between the person and the comparison group, such as on dimensions of gender, ethnicity, and age.

Most behavioral assessors would acknowledge that molar self-report measures can contribute to clinical inferences, when used within a multimethod assessment program and care is taken to address many sources of measurement and inferential error noted above. However, there are several other complications associated with personality assessment: (i) many traits measured by personality assessment instruments are poorly defined and faddish; (ii) molar variables are less likely than molecular variables to reflect the dynamic nature of behavior—they are momentary snap-shots of unstable phenomena; (iii) personality trait measures may be more useful for initial screening than for the construction of a detailed functional analysis and treatment planning; (iv) personality traits can also be conditional: their probability and magnitude can vary across situations; (v) inferences about a client's status on a trait dimension varies across assessment instruments; and (vi) because of their aggregated nature, many response permutations can contribute to a particular score on a trait dimension.

In sum, the integration of person–situation interactional models and personality assessment in the behavioral assessment paradigm can benefit clinical judgments. However, this integration has sometimes occurred too readily, without the thoughtful and scholarly reflection characteristics of the behavioral assessment paradigm.

4.07.7 SUMMARY

Behavioral assessment is a dynamic and powerful assessment paradigm designed to enhance the validity of clinical judgments. One of the most important and complex clinical judgments in behavioral assessment functional analysis—a synthesis of the clinicians hypotheses about the functional relationships relevant to a clients behavior problems. The functional analysis is a central component in the design of behavior therapy programs. The behavioral assessment paradigm suggests that errors in clinical judgments can be reduced to the degree that the judgments are based on multiple assessment methods and sources of information, validated assessment instruments, time-series measurement strategies, data on multiple response modes and parameters, minimally inferential variables, and the assessment of behavior–environment interactions. The Clinical Pathogenesis Map and Functional Analytic Causal Model were introduced as ways of graphically depicting and systematizing the functional analysis.

The methods of behavioral assessment and clinical case conceptualizations are influenced by several interrelated assumptions about the causes of behavior problems. The behavioral assessment paradigm emphasizes multiple causality; multiple causal paths; individual differences in causal variables and paths; environmental causality and reciprocal determinism; contemporaneous causal variables; the dynamic nature of causal relationships; the operation of moderating and mediating variables; interactive and additive causality; situations, setting events, and systems factors as causal variables; and dynamical causal relationships.

The methods of behavioral assessment and clinical case conceptualizations are also affected by assumptions about the characteristics of behavior problems. These include an emphasis on the multimodal and multiparameter characteristics of behavior problems, differences among clients in the importance of behavior problem modes and parameters, the complex interrelationships among a client's multiple behavior problems, and the conditional and dynamic natures of behavior problems.

Three of many methodological foundations of behavioral assessment were discussed: the emphasis on empirical hypothesis-testing, the idiographic emphasis, and the use of time-series assessment strategies.

The decreasing distinctiveness of behavioral and nonbehavioral assessment, and reasons for this change, were discussed. Four caegories of behavioral assessment methods were presented (i) behavioral observation, (ii) self-monitoring, (iii) self-report methods, and (iv) psychophysiological assessment. The specific strategies, conceptual foundations, clinical utility, psychometric properties, disadvantages, technical advancements, and contribution to clinical judgment of each category were presented.

The application of psychometric principles to behavioral assessment was discussed. The applicability of specific principles varies across methods, targets, and applications.

Several issues relating to the integration of behavioral and personality assessment were presented. These included poor definitions for some traits, the molar nature of personality assessment variables, insensitivity to dynamic aspects of behavior, reduced utility for functional analysis and treatment planning, the conditional nature of personality traits, differences among personality assessment instruments, and the aggregated nature of trait measures.

4.08.1 INTRODUCTION

The assessment of intellectual ability has grown and continued to develop and flourish since the nineteenth century. This chapter gives a foundation for understanding the progression of intellectual assessment through a brief historical review of IQ testing. Some of the controversy surrounding intelligence testing will be introduced, and an "intelligent" approach to testing (Kaufman, 1979, 1994b) will be discussed in response to the critics of testing. There are multiple available tests for assessing child, adolescent, and adult intelligence, and this chapter will address a select group of measures. A description and brief overview is provided on the following intelligence tests: Wechsler Primary and Preschool Intelligence Scale-Revised (WPPSI-R; Wechsler, 1989), Wechsler Intelligence Scale for Children-Third Edition (WISC-III; Wechsler, 1974), Wechsler Adult Intelligence Scale-Revised (WAIS-R; Wechsler, 1981), Kaufman Assessment Battery for Children (K-ABC; Kaufman & Kaufman, 1983), Kaufman Adolescent and Adult Intelligence Test (KAIT; Kaufman & Kaufman, 1993), Stanford–Binet: Fourth Edition (Binet IV; Thorndike, Hagen, & Sattler, 1986b), Woodcock-Johnson Psycho-Educational Battery-Revised: Tests of Cognitive Ability (WJ-R; Woodcock & Johnson, 1989), Detroit Tests of Learning Aptitude (DTLA-3; Hammill, 1991), Differential Abilities Scale (DAS; Elliott, 1990), and Das–Naglieri Cognitive Assessment System (CAS; Naglieri & Das, 1996).

A thorough cognitive assessment contains supplemental measures in addition to the main instrument used to measure IQ, as will be discussed later in this chapter. Accordingly, following the description and overview of these multiple instruments is a section which integrates each of them with the Wechsler scales, focusing on how they may be used with Wechsler's tests to further define cognitive functioning. The final part of this chapter provides an illustrative case report that combines a number of different measures in the assessment of a 13-year-old female with academic difficulties.

4.08.1.1 Brief History of Intelligence Testing

Exactly when intelligence testing began is difficult to pinpoint. IQ tests as they are known in the 1990s stem from nineteenth century Europe. Study of the two extremes of intelligence, giftedness and retardation, led to breakthroughs in intellectual assessment. Tracing the roots of assessment, the early pioneers were Frenchmen, who worked with the retarded. In the 1830s, Jean Esquirol distinguished between mental retardation and mental illness, unlumping idiocy from madness (Kaufman, 1983). He focused on language and speech patterns, and even on physical measurements such as the shape on the skull, in testing "feebleminded" and "demented" people.

Another contribution of Esquirol was a system for labeling the retarded. He formed a hierarchy of mental retardation, with "moron" at the top. Those less mentally adept were classified as "imbecile" and those at the bottom rung of intelligence were "idiots." The 1990s classification systems, which use terms like profoundly, severely, or moderately retarded, appear to most as less offensive than Esquirol's labels.

In the mid-1800s, another innovator joined Esquirol in testing retarded individuals. As opposed to Esquirol's use of verbal tests, Edouard Seguin tested these individuals using nonverbal methods, oriented toward sensation and motor activity (Kaufman, 1983). A link between Seguin's work and the twentieth century can be seen, as many of the procedures he developed were adopted or modified by later developers of performance and nonverbal tasks. Intelligence testing and education became intertwined during this time when Seguin convinced authorities of the desirability of educating the "idiots" and "imbeciles." Seguin was also the inspiration for Maria Montessori. Many of his methods and materials are present in the Montessori approach to education.

In an approach similar to Seguin's, stressing discrimination and motor control, Galton studied individual differences in the ordinary man, not just the tail ends of the normal curve. He was committed to the notion that intelligence is displayed through the use of the senses (sensory discrimination and sensory motor coordination), and believed that those with the highest IQ should also have the best discriminating abilities. Therefore, he developed mental tests that were a series of objective measurements of sensory abilities like keenness of sight, color discrimination, and pitch discrimination; sensory motor-abilities like reaction time and steadiness of hand; and motor abilities like strength of squeeze and strength of pull (Cohen, Montague, Nathanson & Swerdlik, 1988).

Galton's theory of intelligence was simplistic: people take in information through their senses, so those with better developed senses ought to be more intelligent. Although his theory of intelligence was quite different than what is considered as intelligence today, he is credited with establishing the first comprehensive individual intelligence test. He also influenced two basic notions of intelligence: the idea that intelligence is a unitary construct, and that individual differences in intelligence are largely genetically determined (possibly influenced by the theory of his cousin, Charles Darwin) (Das, Kirby, & Jarman, 1979).

Galton's concepts were brought to the USA by James McKeen Cattell, an assistant in Galton's laboratory (Roback, 1961). In 1890, Cattell established a Galton-like mental test laboratory at the University of Pennsylvania, and he moved his laboratory to Columbia University in New York the next year. He shared Galton's philosophy that intelligence is best measured by sensory tasks, but expanded his use of "mental tasks" to include standardized administration procedures. He urged for the establishment of norms, and thereby took the assessment of mental ability out of the arena of abstract philosophy and demonstrated that mental ability could be studied experimentally and practically. Studies conducted around the turn of the century at Cattell's Columbia laboratory showed that American versions of Galton's sensory-motor test correlated close to zero with meaningful criteria of intelligence, such as grade-point average in college.

Following Esquirol's lead by focusing on language abilities, Alfred Binet began to develop mental tasks with his colleagues Victor Henri and Theodore Simon (Binet & Henri, 1895; Binet & Simon, 1905, 1908). His tests were complex, measuring memory, judgment, reasoning, and social comprehension, and these tasks survive to the 1990s in most tests of intelligence for children and adults.

The Minister of Public Instruction in Paris appointed Binet to study the education of retarded children in 1904. The Minister wanted Binet to separate retarded from normal children in the public schools. Thus, with 15 years worth of task development behind him, the Binet–Simon scale quickly was assembled (Sattler; 1988).

Binet used a new approach in his tests; he ordered tasks from easy to hard within the scale. In 1908 and 1911 he revised his test to group tasks by age level, to add levels geared for adults, to introduce the concept of mental age, and to give more objective scoring rules (Sattler, 1988). If someone passed the nine-year-old level tasks, but failed the ones at the 10-year level, then that person had the intelligence of the typical nine-year old, whether the person was 6, 9, or 30. The measurement adult's intelligence, except mentally retarded individuals, was almost an after thought. Binet's untimely death in 1911 prevented him from actualizing the many applications of his tests in child development, education, medicine, and research (Kaufman, 1990).

Every IQ test in existence has been impacted greatly by Binet's work, and incorporates many of the same kinds of concepts and test questions that he developed. Lewis Terman was one of several Americans who translated the Binet–Simon for use in the USA. Terman published a "tentative" revision in 1912. Terman then took four years to carefully adapt, expand, and standardize the Binet–Simon. After much painstaking work, in 1916 the Stanford–Binet was born. This test used the concept of mental quotient and introduced the intelligence quotient. The Stanford–Binet left its competitors in the dust, and became the leading IQ test in America.

Like Binet, Terman viewed intelligence tests as useful for identifying "feeblemindedness," or weeding out the unfit. Terman also saw the potential for using intelligence tests with adults for determining ability to perform well in certain occupations. He believed that minimum intelligence quotients were necessary for success in specific occupations.

With the onset of World War I, the field of adult assessment grew quickly due to practical recruitment issues. The USA needed a way to evaluate the mental abilities of thousands of recruits and potential officers in an expedient manner. Due to the large volume of individuals tested, a group version of Binet's test was created by Arthur Otis, a student of Terman. This group-administered Stanford–Binet was labeled the Army Alpha. The Army Beta was also created during World War I to assess anyone who could not speak English or who was suspected of malingering. This was a nonverbal problem solving test, which was a forerunner of today's nonverbal ("Performance") subtests. The Army Alpha and Army Beta tests, published by Yerkes in 1917, were validated on huge samples (nearly two million). The tests were scores "A" to "D-" with the percent scoring "A" supporting their validity: 7% of recruits, 16% of corporals, 24% of sergeants, and 64% of majors. The best evidence of validity, though, was the Peter Principle in action. Second lieutenants (59% "A") outperformed their direct superiors, first lieutenants (53%) and captains (53%), while those with ranks higher than major did not do as well as majors (Kaufman, 1990).

The subtests developed by Binet and World War I psychologists were borrowed by David Wechsler in the mid-1930s to develop the Wechsler-Bellevue Intelligence Scale. His innovation was not in the selection of tasks, but in his idea that IQ was only in part a verbal intelligence. He also assembled a Performance Scale from the nonverbal, visual-motor subtests that were developed during the war to evaluate people who could not speak English very well or whose motivation to succeed was in doubt. Wechsler paired the verbally laden Army Alpha and the Stanford–Binet to create the verbal scale, and the Army Group Examination Beta and the Army Individual Performance scale to create the Performance scale. These two scales together were thought to contribute equally to the overall intelligence scale. The Full Scale IQ, for Wechsler, is an index of general mental ability (*g*).

To Wechsler, these tests were dynamic clinical instruments, more than tools to subdivide retarded individuals (Kaufman, 1990). However, the professional public was leery. They wondered how tests developed for the low end of the ability spectrum could be used to test normal people's intelligence. The professionals and publishers had a difficult time accepting that nonverbal tests could be used as measures for all individuals, not just foreigners. The postwar psychological community held the belief that IQ tests were primarily useful for predicting children's success in school, but were critical of Wechsler for developing a test primarily for adolescents and adults.

He persisted with his idea that people with poor verbal intelligence may be exceptional in their nonverbal ability, and vice versa. He met with resistance and frustration, and could not find a publisher willing to subsidize his new test. Thus, with a group of psychologist friends, Weschler tested nearly 2000 children, adolescents, and adults in Brooklyn, New York. Although it was a very urban sample, he managed to obtain a well stratified sample.

Once it had been standardized, Wechsler had no problem finding a publisher in The Psychological Corporation. The original Wechsler-Bellevue (Wechsler, 1939) has grandchildren, including the Wechsler Intelligence Scale for Children-Revised (WISC-R), and the Wechsler Adult Intelligence Scale-Revised (WAIS-R); more recently in 1991 a great-grandchild was born, the WISC-III.

Loyalty to the Stanford–Binet prevented Wechsler's test from obtaining instant success. However, gradually, Wechsler overtook the Binet during the 1960s as the learning disabilities movement gained popularity. The Verbal IQ and Performance IQ provided by Wechsler's tests helped to identify bright children who had language difficulties or visual-perceptual problems. The Stanford–Binet offered just one IQ, and the test was so verbally oriented that people with exceptional nonverbal intelligence were penalized.

Terman's Stanford–Binet lost favor when revisions of the battery after his death in 1956 proved to be expedient and shortsighted. In the 1990s, Wechsler's scales have proven themselves by withstanding challenges by other test developers, including the Kaufman Assessment Battery for Children (K-ABC) (Kaufman & Kaufman, 1983), the Kaufman Adolescent and Adult Intelligence Test (KAIT) (Kaufman & Kaufman, 1993), the Differential Abilities Scale (DAS) (Elliott, 1990), and Woodcock–Johnson (Woodcock & Johnson, 1989). These many other tests are used widely, but generally remain as alternatives or supplements to the Wechsler scales.

4.08.1.2 Controversy Over Intelligence Testing

The measurement of intelligence has long been the center of debate. In the past, critics have spoken of IQ tests as "biased," "unfair," and "discriminatory." The critics' arguments in the 1990s center more around what the IQ tests truly measure, as well as how or if they should be interpreted, their relevance to intervention, and their scope. Despite the controversy, there is great interest and need for measurement of intelligence, especially in the educational context, in order to help children and adolescents. Amidst the criticisms and limitations of IQ testing, these instruments remain a most technologically advanced and sophisticated tool of the profession for providing essential and unique information to psychologists so they may best serve the needs of children and adults. When used in consideration of the American Psychological Association's Ethical Principles of Psychologists (American Psychological Association, 1990) Principle 2-Competence, which encourages clinicians to recognize differences among people (age, gender, socioeconomic, and ethnic backgrounds) and to understand test research regarding the validity and the limitations of their assessment tools, these tests can be beneficial despite the controversy.

Three controversial themes associated with IQ testing were noted by Kaufman (1994). The first involves opposition to the common practice of subtest interpretation advocated by Wechsler (1958) and Kaufman (1979, 1994b). The second includes those who would abandon the practice altogether. Finally, the third group suggests that the concept of intelligence testing is sound, but more contemporary instrumentation could improve the effectiveness of the approach.

The first group of psychologists has encouraged practitioners to "just say 'no' to subtest analysis" (McDermott, Fantuzzo, & Glutting, (1990) (p. 299; also see Glutting, McDermott, Prifitera, & McGrath, (1994), and Watkins & Kush, (1994)). McDermott and his colleagues argue that interpreting a subtest profile is in violation of the principles of valid test interpretation because the ipsative method fails to improve prediction (McDermott, Fantuzzo, Glutting, Watkins, & Baggaley, 1992) and therefore does not augment the utility of the test. It is agreed that the results of studies conducted by McDermott et al. (1992), do suggest that using the WISC-III in isolation has limitations, but using the ipsative approach in conjunction with other relevant information such as achievement test results and pertinent background information may be beneficial. Kaufman (1994) further suggests that by shifting to the child's midpoint score a more equally balanced set of hypotheses can be developed which can be integrated with other findings to either strengthen or disconfirm hypotheses. When the ipsative assessment approach is used to create a base from which to search for additional information to evaluate hypothesized strengths and weaknesses in the child's subtest profile its validity is extended beyond that which can be obtained using the Wechsler subtests alone. If support is found for the hypotheses, then such a strength or weakness can be viewed as reliable, because of its cross-validation (Kaufman, 1994). When considering this position and that represented by McDermott et al., as well as Glutting et al. (1994) and Watkins and Kush (1994), it is important to recognize that these authors are against subtest profile analysis not the use of IQ tests in general. This is in contrast to others who hold a more extreme negative view of IQ testing.

One extremist group that opposes IQ testing includes those who advocate throwing away Verbal and Performance IQs, along with the subtest profile interpretation, and finally the Full Scale IQ because they insist that all that Wechsler scales measure is *g* (MacMann & Barnett, 1994). They argue that differences between the Verbal and Performance Scales on Wechsler tests hold no meaning, that conventional intelligence tests only measure *g* (and a measure of *g* is not enough to warrant the administration of such an instrument) and that Wechsler scale data do not have instructional value. These authors fail to recognize a wealth of data that illustrates that differences between the Verbal and Performance Scales can be very important. Any clinician using intelligence tests cannot ignore the numerous studies that are available that point to significant Verbal Performance differences in patients with right-hemisphere damage (Kaufman, 1990, Chapter 9), in Hispanic and Navajo children (McShane & Cook, 1985; McShane & Plas, 1984; Naglieri, 1984), and in normal adults (Kaufman, 1990, Chapter 7). If only the Full Scale IQ is interpreted, following MacMann and Barnett's (1994) advisement that the Verbal and Performance scales are meaningless, then it prevents the fair use of these tests with those groups who have inconsistent V–P discrepancies. Moreover, contrary to what MacMann and Barnett (1994) suggest, it is clear that when a child earns very poor Verbal and average Performance scores there are obvious implications for instruction and a high probability that such results will be reflected in poor verbal achievement (Naglieri, 1984).

Another extremist group opposed to IQ testing is Witt and Gresham (1985) who state, "The WISC-R lacks treatment validity in that its use does not enhance remedial interventions for children who show specific academic skill deficiencies" (p. 1717). It is their belief that the Wechsler test should be replaced with assessment procedures that have more treatment validity. However, as Kaufman (1994) points out, Witt and Gresham (1985) do not provide evidence for their statements. Another pair of researchers (Rechsly & Tilly, 1993) agree with the Witt and Gresham (1985) statements about the lack of treatment validity of the WISC-R, but only provide references that are not specific to the Wechsler scales. Thus, the Wechsler scales appear to have been rejected by these researchers without ample relevant data.

Witt and Gresham (1985) also complain that the WISC-R (as well as the WISC-III) only yields a score, and does not provide school psychologists with direct strategies of what to do with and for children, which are what teachers are requesting. As Kaufman (1994) points out, however, it is not the instrument's responsibility to provide direct treatment information; rather, he states, "It is the examiner's responsibility ... to provide recommendations for intervention" (p. 35). The examiner should not be just taking the bottom-line IQ scores or standard scores, but should provide statements about a child's strengths and weaknesses that have been cross-validated through the observations of behavior, background information, and the standardized intelligence and achievement tests.

Finally, there is a group of professionals who have suggested that the Wechsler has limits that should be recognized, but these limits could be addressed by alternative methods rather than abandoning the practice of intelligence testing altogether. Some have argued for a move toward alternative conceptualizations of intelligence and methods to measure new constructs that are based on factor analytic research (e.g., Woodcock, 1990) while others have used neuropsychology and cognitive psychology as a starting point (e.g., Naglieri & Das, 1996). The results of these efforts have been tests such as the Das–Naglieri Cognitive Assessment System

(Naglieri & Das, 1996), Kaufman Assessment Battery for Children (Kaufman & Kaufman, 1983), Kaufman Adult Intelligence Test (Kaufman & Kaufman, 1993), and the Woodcock–Johnson Tests of Cognitive Ability (Woodcock & Johnson, 1989). This chapter will show how these tests, and others, can be utilized in conjunction with the Wechsler to gain a more complete view of the child.

The main goal of this chapter is to use Kaufman's (1994) philosophy of "intelligent" testing to address some of the concerns about Wechsler interpretation through a careful analysis of the results and integration with other measures. Much of this discussion is based on the principles of IQ testing as outlined by Kaufman, which focus on the view that "WISC-III assessment is of the individual, by the individual, and for the individual" (Kaufman, 1994, p. 14). Through research knowledge, theoretical sophistication, and clinical ability examiners must generate hypotheses about an individual's assets and deficits and then confirm or deny these hypotheses by exploring multiple sources of evidence. Well-validated hypotheses must then be translated into meaningful, practical recommendations. A brief description of those five principles of intelligent testing follows.

Clinician-scientists must come well equipped with state of the art instrumentation, good judgment, knowledge of psychology, and clinical training to move beyond the obtained IQs (Kaufman, 1994). Integration of information from many sources and different tests is very important if the child referred for evaluation is to remain the focus of assessment because it is impossible to describe fully a person by just presenting a few numbers from the Wechsler protocol or those obtained from a computer program. Each adult and child who comes for an assessment has unique characteristics, a particular way of approaching test items, and may be affected differently by the testing situation than the next individual. Through the use of an integrated interpretation approach the various dimensions that influence a child can become apparent.

4.08.1.3 Principles of the Intelligent Testing Philosophy

The first principle of intelligent testing is that "the WISC-III subtests measure what the individual has learned" (Kaufman, 1994, p. 6). The WISC-III is like an achievement test, in that it is a measure of past accomplishments and is predictive of success in traditional school subjects. Research indicates that intelligence tests consistently prove to be good predictors of conventional school achievement. The WISC-III Manual (Wechsler, 1991, pp. 206–209) gives many such correlations between the WISC-III IQs or Factor Indexes and achievement measures. Although this connection between the WISC-III and achievement in school is well documented empirically, it should not be accepted ultimately as a statement of fate, that if a child scores poorly on the WISC-III that they will do poorly in school (Kaufman, 1994). Instead, constructive interpretation of a test battery can lead to recommendations which may alter helpfully a child's development.

The second principle is that WISC-III subtests are samples of behavior and are not exhaustive. Because the subtests only offer a brief glimpse into a child's overall level of functioning, examiners must be cautious in generalizing the results to performance and behaviors in other circumstances. The Full Scale "should not be interpreted as an estimate of a child's global or total intellectual functioning; and the WISC-III should be administered along with other measures, and the IQs interpreted in the context of other test scores" (Kaufman, 1994, p. 7). It is important that the actual scores are not emphasized as the bottom-line; rather, it is more beneficial to elaborate on what children can do well, relative to their own level of ability. Such information can be used to create an individualized education program which will tap a child's areas of strength and help improve areas of deficit.

Principle three states, "The WISC-III assesses mental functioning under fixed experimental conditions" (Kaufman, 1994, p. 8). Rigid adherence to the standardized procedures for administration and scoring, outlined in the WISC-III manual (Wechsler, 1991), helps to ensure that all children are measured in an objective manner. However, parts of the standardized procedure make the testing situation very different than a natural setting. For example, it is not very often in a children's every day life that someone is transcribing virtually every word they say or timing them with a stopwatch. The standardization procedures are important to follow, but must be taken into account as limitations when interpreting the scores obtained in the artificial testing situation. The value of the intelligence test is enhanced when the examiner can meaningfully relate observations of the child's behaviors in the testing situation to the profile of scores.

The fourth principle is that "The WISC-III is optimally useful when it is interpreted from an information-processing model" (Kaufman, 1994, p. 10). This is especially beneficial for helping to hypothesize functional areas of strength and dysfunction. This model suggests examining how information enters the brain from the sense organs (input), how information is interpreted and processed (integration), how information is stored for later retrieval (storage), and how information is expressed linguistically or motorically (output). Through this model, examiners can organize the test data, including fluctuations in subtest scores, into meaningful underlying areas of asset and deficit.

The fifth and very important principle of intelligent testing is that, "Hypotheses generated from WISC-III profiles should be supported with data from multiple sources" (Kaufman, 1994, p. 13). Although good hypotheses can be raised from the initial WISC-III test scores, such hypotheses do not hold water unless verified by diverse pieces of data. Such supporting evidence may come from careful observation of a child's behavior during test administration; from the pattern of responses across various subtests; from background information obtained from parents, teachers, or other referral sources; from previous test data; and from the administration of supplemental subtests. The integration of data from all these different sources is critical in obtaining the best and most meaningful clinical interpretation of a test battery.

4.08.2 MEASURES OF INTELLIGENCE

Intelligence tests are administered for a variety of reasons including identification (of mental retardation, learning disabilities, other cognitive disorders, giftedness), placement (gifted and other specialized programs), and as a cognitive adjunct to a clinical evaluation. The following comprehensive intelligence tests are discussed in the next sections: WPPSI-R, WISC-III, WAIS-R, K-ABC, KAIT, Binet-IV, WJ-R Tests of Cognitive Ability, DTLA-3, DAS, and CAS.

4.08.2.1 Wechsler's Scales

As discussed in the brief history of IQ tests, Wechsler's scales reign as leaders of measures of child, adolescent, and adult intelligence. The WISC-III is a standard part of a battery administered to children by school psychologists and private psychologists to assess level cognitive functioning, learning styles, learning disabilities, or giftedness. The WAIS-R is administered invariably as a part of a battery to assess intellectual ability for a clinical, neurological, or vocational evaluation of adolescents and adults. The WPPSI-R may be used to measure intellectual ability from ages three to seven years, three months; intellectual assessment may be done from age six up to age 16 with the WISC-III, while the WAIS-R may be used from ages 16–74.

The different Wechsler scales overlap at ages 6–7 and 16. Kaufman (1994) recommends that the WISC-III be used at both these overlapping age periods rather than the WPPSI-R or the WAIS-R. One of the reasons cited for these recommendations is that the WISC-III has a much better "top" than the WPPSI-R for children who are ages six or seven. On the WPPSI-R a child can earn a maximum score of 16 or 17 (rather than 19) on six of the 10 subtests when age seven. The recommendation to use the WISC-III rather than the WAIS-R at age 16 is made because the WAIS-R norms are outdated relative to the WISC-III norms. Kaufman (1990) recommends that the WAIS-R norms for ages 16–19 be used cautiously, and states that the "even apart WISC-III norms, the Performance scale is more reliable for the WISC-III (0.92) than the WAIS-R (0.88) at age 16" (p. 40).

Wechsler (1974) puts forth the definition that "intelligence is the overall capacity of an individual to understand and cope with the world around him [or her]" (p. 5). His tests, however, were not predicated on this definition. Tasks developed were not designed from well-researched concepts exemplifying his definition. In fact, as previously noted, virtually all of his tasks were adapted from other existing tests.

Like the Binet, Wechsler's definition of intelligence also ascribes to the conception of intelligence as an overall global entity. He believed that intelligence cannot be tested directly, but can only be inferred from how an individual thinks, talks, moves, and reacts to different stimuli. Therefore, Wechsler did not give credence to one task above another, but believed that this global entity called intelligence could be ferreted out by probing a person with as many different kinds of mental tasks as one can conjure up. Wechsler did not believe in a cognitive hierarchy for his tasks, and he did not believe that each task was equally effective. He felt that each task was necessary for the fuller appraisal of intelligence.

4.08.2.1.1 Wechsler Primary and Preschool Intelligence Scale-Revised (WPPSI-R)

(i) Standardization and properties of the scale

The WPPSI-R is an intelligence test for children aged three years, through seven years, three months. The original version of the WPPSI was developed in 1967 for ages four to six and a half years, and the WPPSI-R was revised in 1989. Several changes were made to the revised version of the WPPSI-R. The norms were updated, the appeal of the content to young children was improved, and the age range was expanded.

The WPPSI-R is based on the same Wechsler–Bellevue theory of intelligence, emphasizing intelligence as a global capacity but having Verbal and Performance scales as two methods of assessing this global capacity (Kamphaus, 1993). The Verbal scale subtests include: Information Comprehension, Arithmetic, Vocabulary, Similarities, and Sentences (optional subtest). The Performance scale subtests include: Object Assembly, Block Design, Mazes, Picture Completion, and Animal Pegs (optional subtest).

Like the K-ABC and the Differential Abilities Scales (DAS), the WPPSI-R allows the examiner to "help" or "teach" the client on early items on the subtests to assure that the child understands what is expected. Providing this extra help is essential when working with reticent preschoolers (Kamphaus, 1993).

Subtest scores have a mean of 10 and a standard deviation of three. The overall Verbal, Performance, and Full Scale IQs have a mean of 100 and a standard deviation of 15. The examiner manual provides interpretive tables that allow the examiner to determine individual strengths and weaknesses as well as the statistical significance and clinical rarity of Verbal and Performance score differences.

The WPPSI-R was standardized on 1700 children from age three through seven years, 3 months. The standardization procedures followed the 1986 US Census Bureau estimates. Stratification variables included gender, race, geographic region, parental occupation, and parental education.

The WPPSI-R appears to be a highly reliable measure. The internal consistency coefficients across age groups, for the Verbal, Performance, and Full Scale IQs are 0.95, 0.92, and 0.96, respectively. For the seven-year-old age group, the reliability coefficients are somewhat lower. The internal consistency coefficients for the individual Performance subtests vary from 0.63 for Object Assembly to 0.85 for Block Design, with a median coefficient of 0.79. The internal consistency coefficients for the individual Verbal subtests vary from 0.80 for Arithmetic to 0.86 for Similarities, with a median coefficient of 0.84. The test–retest coefficient for the Full Scale IQ is 0.91.

The WPPSI-R manual provides some information on validity; however, it provides no information on the predictive validity of the test. Various studies have shown that concurrent validity between the WPPSI-R and other tests is adequate. The correlation between the WPPSI and the WPPSI-R Full Scale IQs was reported at 0.87, and the correlations between WPPSI-R and WISC-III Performance, Verbal, and Full Scale IQs for a sample of 188 children were 0.73, 0.85, and 0.85, respectively. The correlations between the WPPSI-R and other well known cognitive measures are, on average, much lower. The WPPSI-R Full Scale IQ correlated 0.55 with the K-ABC Mental Processing Composite (Kamphaus, 1993) and 0.77 with the Binet IV Test Composite (McCrowell & Nagle, 1994). In general, the validity coefficients provide strong evidence for the construct validity of the WPPSI-R (Kamphaus, 1993).

(ii) Overview

The WPPSI-R is a thorough revision of the 1967 WPPSI, with an expanded age range, new colorful materials, new item types for very young children, a new icebreaker subtests (Object Assembly), and a comprehensive manual (Kaufman, 1990). The revision of the test has resulted in an instrument that is more attractive, more engaging, and materials that are easier to use (Buckhalt, 1991; Delugach, 1991).

The normative sample is large, provides recent norms and is representative of the 1986 US Census data (Delugach, 1991; Kaufman, 1990). The split-half reliability of the IQs and most subtests are exceptional, the factor analytic results for all age groups are excellent, and the concurrent validity of the battery is well supported by several excellent correlational studies (Delugach, 1991; Kaufman, 1990). The manual provides a number of validity studies, factor analytic results, research overviews, and state-of-the-art interpretive tables, which provide the examiner with a wealth of information. Kaufman (1990) noted that the WPPSI-R has a solid psychometric foundation.

In spite of its reported strengths, the WPPSI-R has flaws. In publishing the WPPSI-R, great effort was made to ensure that all subtests had an adequate "top" and "bottom" (Kaufman, 1992). However, the WPPSI-R has an insufficient floor at the lowest age levels, which limits the test's ability to diagnose intellectual deficiency in young preschoolers (Delugach, 1991). For example, a child at the lowest age level (2–11–16 to 3–2–15) who earns only one point of credit on all subtests will obtain a Verbal IQ of 75, a Performance IQ of 68, and a Full Scale IQ of 68, making it impossible to adequately assess the child's degree of intellectual deficiency. The WPPSI-R subtests are able to distinguish between gifted and nongifted children at all ages, but the top of some subtests is not adequate to discriminate among gifted children. Kaufman (1992) indicates that at the youngest ages (3–4.5 years), all subtests are excellent. However, at age five, Geometric Design begins to falter, and at ages 6.5 and above, it only allows a maximum scaled score of 16. Other subtests, such as Object Assembly and Arithmetic also have problems with the ceiling. Although the ceilings on the subtests described are not ideal, the IQ scales do allow maximum IQs of 150 for all ages and IQs of 160 for children ages 3–6.25.

Another major problem with the WPPSI-R is the role played by speed of responding. From both early developmental perspectives and common-sense perspectives, giving bonus points for speed is silly (Kaufman, 1992). Young children may respond slowly for a variety of reasons that have little to do with intellect. A three- or four-year-old child might respond slowly or deliberately because of lack immaturity, lack of experience in test taking, underdeveloped motor coordination, or a reflective cognitive style. The WPPSI-R Object Assembly and Block Design place an overemphasis on speed. For example, if a six and a half or seven year old child solves every Object Assembly item perfectly, but does not work quickly enough to earn bonus points, they would only receive a scaled score of 6 (ninth percentile). Because of the age-inappropriate stress on solving problems in with great speed, a child's IQ may suffer on two of the 10 subtests (Kaufman, 1992). In addition, the directions on some of the Performance subtests are not suitable for young children because they are not developmentally appropriate (Kaufman, 1990). However, Delugach (1991) reports that if the directions are too difficult, the test provides procedures to ensure that the child understands the demands of the task.

The WPPSI-R is a useful assessment tool, but, like all others, it possesses certain weaknesses that limit its usefulness (Delugach, 1991). Examiners should be aware of the WPPSI-R's inherent strengths and weaknesses and keep them in mind during administration, scoring, and interpretation. The WPPSI-R may provide the examiner with useful information; however, "it does little to advance our basic understanding of the development and differentiation of intelligence or our understanding of the nature of individual differences in intelligence" (Buckhalt, 1991).

4.08.2.1.2 Wechsler Intelligence Scale for Children-3rd Edition (WISC-III)

(i) Standardization and properties of the scale

The WISC-III was standardized on 2200 children ranging in age from six through 16 years. The children were divided into 11 age groups, one group for each year from six through 16 years of age. The median age for the each age group was the sixth month (e.g., 7 years, 6 months). The standardization procedures followed the 1980 US Census data and the manual provides information by age, gender, race/ethnicity, geographic region, and parent education. "Overall, the standardization of the WISC-III is immaculate ... a better-standardized intelligence test does not exist" (Kaufman, 1993, p. 351).

The WISC-III yields three IQs, a Verbal Scale IQ, a Performance Scale IQ, and a Full Scale IQ. All three are standard scores (mean of 100 and standard deviation of 15) obtained by comparing an individual's score with those earned by the representative sample of age peers. Within the WISC-III, there are 10 mandatory and three supplementary subtests all of which span the age range of six through 16 years. The Verbal scale's five mandatory subtests include: Information, Similarities, Arithmetic, Vocabulary, and Comprehension. The supplementary subtest on the Verbal Scale is Digit Span. Digit Span is not calculated into the Verbal IQ unless it has been substituted for another Verbal subtest because one of those subtests has been spoiled (Kamphaus, 1993; Wechsler, 1991).

The five mandatory Performance scale's subtests include Picture Completion, Picture Arrangement, Block Design, Object Assembly, and Coding. The two supplementary subtest on the Performance scale are Mazes and Symbol Search. The Mazes subtest may be substituted for any Performance scale subtest; however, Symbol Search may only be substituted for the Coding subtest (Kamphaus, 1993; Wechsler, 1991).

"Symbol Search is an excellent task that should have been included among the five regular Performance subtests instead of Coding. Mazes is an awful task that should have been dropped completely from the WISC-III" (Kaufman, 1994, p. 58). He goes further to say that "there's no rational reason for the publisher to have rigidly clung to Coding as a regular part of the WISC-III when the new Symbol Search task is clearly a better choice for psychometric reasons" (p. 59). Therefore, for all general purposes, Kaufman (1994) strongly recommends that Symbol Search be substituted routinely for coding as part of the regular battery, and to use Symbol Search to compute the Performance IQ and Full Scale IQ. The manual does not say to do this, but neither does it prohibit it.

Reliability of each subtest except Coding and Symbol Search was estimated by the split-half method. Stability coefficients were used as reliability estimates for the Coding and Symbol Search subtests because of their speeded nature.

Across the age groups, the reliability coefficients range from 0.69 to 0.87 for the individual subtests. The average reliability, across the age groups, for the IQs and Indexes are: 0.95 for the Verbal IQ, 0.91 for the Performance IQ, 0.96 for the Full Scale IQ, 0.94 for the Verbal Comprehension Index, 0.90 for the Perceptual Organization Index, 0.87 for the Freedom from Distractibility Index and 0.85 for the Processing Speed Index (Wechsler, 1991).

Factor analytic studies of the WISC-III standardization data were performed for four age group subsamples: ages 6–7 (n = 400), ages 8–10 (n = 600), ages 11–13 (n = 600), and ages 14–16 (n = 600) (Wechsler, 1991). Compiling the results of the analysis, a four-factor solution was found for the WISC-III. Like the WISC-R, Verbal Comprehension and Perceptual Organization remain the first two factors. Verbal Comprehension involves verbal knowledge and the expression of this knowledge. Perceptual Organization, a nonverbal dimension, involves the ability to interpret and organize visually presented material. The third factor consists of the Arithmetic and Digit Span subtests. Factor III has been described as Freedom from Distractibility since common among tasks is the ability to focus, to concentrate, and to remain attentive. Other interpretations of this factor have included facility with numbers, short-term memory, and sequencing because the three tasks which comprise the factor all involve a linear process whereby numbers are manipulated. Success is either facilitated by or wholly dependent on memory (Kaufman, 1979). The fourth factor consists of Coding and Symbol Search, and is referred to as the Processing Speed factor. Taken together, the Verbal Comprehension and Perceptual Organization factors offer strong support for the construct validity of the Verbal and Performance IQs; substantial loadings on the large, unrotated first factor (g) supports the construct underlying Wechsler's Full Scale IQ.

(ii) Analyzing the WISC-III data

To obtain the most information from the WISC-III, the psychologist should be more than familiar with each of the subtests individually as well as with the potential information that those subtests can provide when integrated or combined. The WISC-III is maximally useful when tasks are grouped and regrouped to uncover a child's strong and weak areas of functioning, so long as these hypothesized assets and deficits are verified by multiple sources of information.

As indicated previously, the WISC-III provides examiners with a set of four Factor Indexes in addition to the set of three IQs. The front page of the WISC-III record form lists the seven standard scores in a box on the top right. The record form is quite uniform and laid out nicely; however, it is difficult to know just what to do with all of those scores. Kaufman (1994) has developed seven steps to interpretation which offer a systematic method of WISC-III interpretation that allows the clinician to organize and integrate the test results in a step-wise fashion. The seven steps (see Table 1) provide an empirical framework for profile attack while organizing the profile information into hierarchies.

(iii) Overview

Professionals in the field of intelligence testing have described the third edition of the Wechsler Intelligence Scale for Children in a number of different ways. Some critics feel that the WISC-III reports continuity, the status quo, but makes little progress in the evolution of the assessment of intelligence. Such critics note that despite more than 50 years of advancement in theories of intelligence, the Wechsler philosophy of intelligence (not actually a formal theory), written in 1939, remains the guiding principle of the WISC-III (Schaw, Swerdilik, & Laurent, 1993). One of the principal goals for developing the WISC-III stated in the manual was merely to update the norms, which is "hardly a revision at all" (Sternberg, 1993). Sternberg (1993) suggests that the WISC-III is being used to look for a test of new constructs in intelligence, or merely a new test, the examiner should look elsewhere.

In contrast to these fairly negative evaluations, Kaufman (1993) reports that the WISC-III is a substantial revision of the WISC-R and that the changes that have been made are considerable and well done. "The normative sample is exemplary, and the entire psychometric approach to test development, validation, and interpretation reflects sophisticated, state-of-the-art knowledge and competence" (Kaufman, 1993). For Kaufman, the WISC-III is not without its flaws but his overall review of the test is quite positive. One of Kaufman's (1993) main criticisms is that the Verbal tasks are highly culturally-saturated and school-related, which tend to penalize bilingual, minority, and learning-disabled children. He suggests that perhaps a special scale could have been developed to provide a fairer evaluation of the intelligence of children who are from the non-dominant culture or who have academic difficulties. Another criticism raised by Kaufman is that too much emphasis is (placed on a child's speed of responding on the WISC-III. It is difficult to do well on the WISC-III if you do not solve problems very quickly. This need for

Table 1 Summary of seven steps for interpreting WISC-III profiles.

Step	
1	*Interpret the full scale IQ* Convert it to an ability level and percentile rank and band it with error, preferable a 90% confidence interval (about ± 5 points)
2	*Determine if the verbal-performance IQ discrepancy is statistically significant* Overall values for V–P discrepancies are *11 points* at the 0.05 level and *15 points* at the 0.01 level. For most testing purposes, the 0.05 level is adequate
3	Determine if the V–P IQ discrepancy is interpretable, or if the VC and PO factor indexes should be interpreted instead Ask four questions about the Verbal and Performance Scales *Verbal Scale* (i) Is there a significant difference ($p < 0.05$) between the child's standard scores in VC vs. FD? size needed for significant (VC–FD) = 13+ points (ii) Is there abnormal scatter (highest minus lowest scaled score) among the five Verbal subtests used to compute V-IQ? Size needed for abnormal verbal scatter = 7+ points *Performance Scale* (iii) Is there a significant difference ($p < 0.05$) between the child's standard scores on PO vs. PS? Size needed for significant (PO–PS) = 15+ points (iv) Is there abnormal scatter (highest minus lowest scaled score) among the five Performance subtests used to compute P-IQ? Size needed for abnormal performance scatter = 9+ points If all answers are no, the V–P IQ discrepancy is interpretable. If the answer to one or more questions is yes, the V–P IQ discrepancy may not be interpretable. Examine the VC–PO discrepancy. Overall values for VC–PO discrepancies are *12 points* at the 0.05 level and *16 points* at the 0.01 level Determine if the VC and PO indexes are unitary dimensions: 1. Is there abnormal scatter among the four VC subtests? Size needed for abnormal VC scatter = 7+ points 2. Is there abnormal scatter among the four PO subtests? Size needed for abnormal PO scatter = 8+ points If the answer to either question is yes, then you probably shouldn't interpret the VC–PO Index discrepancy – unless the discrepancy is to big to ignore (see Step 4). If both answers are no, interpret the VC–PO differences as meaningful
4	*Determine if the V–P IQ discrepancy (or VC–PO discrepancy) Is abnormally large* Differences of at least *19 points* are unusually large for both the V–P and VC-PO discrepancies. Enter the table with the IQs or Indexes, whichever was identified by the questions and answers in Step 3 If neither set of scores was found to be interpretable in Step 3, they may be interpreted anyway if the magnitude of the discrepancy is unusually large (19+ points)
5	*Interpret the meaning of the global verbal and nonverbal dimensions and the meaning of the small factors* Study the information and procedures presented in Chapter 4 (verbal/nonverbal) and Chapter 5 (FD and PS factors). Chapter 5 provides the following rules regarding when the FD and PS factors have too much scatter to permit meaningful interpretation of their respective Indexes (both Chapters 4 and 5 are on *Intelligent Testing with the WISC-III*): (i) Do not interpret the FD Index if the Arithmetic and Digit Span scaled scores differ by *four or more points* (ii) Do not interpret the PO Index if the Symbol Search and Coding scaled scores differ by *four or more points*
6	*Interpret significant strengths and weaknesses in the WISC-III subtest profile* If the V–P IQ discrepancy is less than 19 points, use the child's mean of all WISC-III subtests administered as the child's midpoint If the V–P IQ discrepancy is 19 or more points, use the child's mean of all Verbal subtests as the midpoint for determining strengths and weaknesses on Verbal subtests, and use the Performance mean for determining significant deviations on Performance subtests Use either the specific values in Table 3.3 of *Intelligent Testing with the WISC-III*, rounded to the nearest whole number, or the following summary information for determining significant deviations: ±3 points: Information, similarities, arithmetic, vocabulary ±4 points: Comprehension, digit span, picture completion, picture arrangement, block design, object assembly, symbol search ±5 points: Coding
7	*Generate hypotheses about the fluctuations in the WISC-III subtest profile* Consult Chapter 6 in *Intelligent Testing with the WISC-III*, as it deals with the systematic reorganization of subtest profiles to generate hypotheses about strengths and weaknesses

speed penalizes children who are more reflective in their cognitive style or who have coordination difficulties. The speed factor may prevent a gifted child from earning a high enough score to enter into an enrichment class or may lower a learning disabled child's overall IQ score to a below average level, just because they do not work quickly enough. Although the WISC-III clearly has had mixed reviews, it is one of the most frequently used tests in the field of children's intelligence testing.

4.08.2.1.3 WISC-III Short Form

Short forms of the Wechsler scales were developed shortly after the original tests were developed (Kaufman, Kaufman, Balgopal, & McLean, 1996). Short forms are designed to have sound psychometric qualities and clinical justification, but should also be practical to use. Clinicians and researchers utilize short form when wanting to perform a screen of intellectual ability or when doing research which does not permit the needed time to complete an entire Wechsler scale. In a study using three different WISC-III short forms, the clinical, psychometric, and practical qualities for each form were examined (Kaufman, Kaufman, Balgopal et al. 1996). A psychometric and clinically strong short form was examined, and included the following subtests: Similarities, Vocabulary, Picture Arrangement, and Block Design. A practical short form, based on its brevity and ease of scoring, included the following subtests: Information, Arithmetic, Picture Completion, and Symbol Search. A short form which combines psychometric, clinical, and practical qualities was also examined: Similarities, Arithmetic, Picture Completion, and Block Design.

The results of this study using the WISC-III standardization sample of 2200 children, 6–16 years old, revealed important information about the utility of these three different short forms (Kaufman, Kaufman, Balgopal et al., 1996). The split-half reliability coefficients, standard error of measurement (SEM), validity coefficients, and standard errors of estimate for the three selected tetrads are presented in Table 2. The form which had both psychometric and clinical properties (S-V-PA-BD) was compared to the form which had the quality of practicality in addition to psychometric and clinical properties (S-A-PC-BD). The results indicated that they were equally valid and about equally reliable (see Table 2). Each of the three short form tetrads had reliability coefficients of above 0.90 for the total sample. The brief tetrad (I-A-PC-SS) had a lower correlation with the Full Scale of 0.89, compared to the other two forms which each correlated 0.93 with the Full Scale. Although they were each about equally reliable, the S-A-PC-BD subtests are quicker to administer and only Similarities requires some subjectivity to score. It is quicker to score than the S-V-PA-BD form because it uses Arithmetic instead of Vocabulary.

The authors recommend that the extra 25–30% savings in time in using the S-A-PC-BD form, in addition to the added validity in comparison to the practical tetrad (I-A-PC-SS), makes the S-A-PC-BD short form an excellent choice. The very brief practical form was not recommended for clinical use or screening purposes because of its lower validity. Kaufman, Kaufman, Balgopal, et al. (1996) present an equation for converting a person's sum of scaled scores of the four subtests to estimated FSIQs. The magnitude of the intercorrelations among the component subtests provide that data from which the exact equation is derived. The intercorrelations vary to some extent as a function of age, which leads to slightly different equations at different ages. However, the authors state that the equations for the total sample for each tetrad represent a good overview for all children ages 6–16. The following conversion equation is for the total sample for the recommended S-A-PC-BD short form:

Estimated FSIQ = $1.6c + 36$, (for other specific equations for varying ages, see Kaufman, Kaufman, Balgopal et al., 1996, p. 103).

To use this conversion equation, the child's scaled scores on the four subtests (S-A-PC-BD) must first be summed. The sum (Xc) must then be entered into the equation. For example, if examiners give the recommended psychometric/clinical/practical form to an eight-year-old, the child's scores on the four subtests would need to be summed. Suppose that the child's sum is 50. The above equation would show:

$$\begin{aligned}\text{Estimated FSIQ} &= 1.6(50) + 36\\ &= 80 + 36 = 116\end{aligned}$$

It is important to note that examiners should not take the good psychometric qualities of the short form to mean that the short form can be regularly substituted for the complete battery. There is a wealth of information, both clinical and psychometric, that the examiner benefits from when administering the complete battery. It is important not to favor the short forms just because they are shorter, on account of all the important information that is derived from a complete administration. Kaufman (1990) suggests that the following are a few instances in which the savings in administration time may justify use of the short form: (i) when only a

global assessment of IQ is needed in the context of a complete personality evaluation; (ii) when a thorough evaluation has been completed recently and just a brief check of present intellectual functioning is needed; and (iii) when an individual does not require categorization of their intellectual ability for placement or for diagnosis of a cognitive disorder.

4.08.2.1.4 Wechsler Adult Intelligence Scale-Revised (WAIS-R)

The Wechsler Adult Intelligence Scale-Third Edition (WAIS-III; The Psychological Corporation, 1997) came out in August 1997 and soon will be replacing the WAIS-R. Based on our experience with previous versions of the WAIS, it is likely that there will be a transition period of 3–4 years during which time clinicians will be gradually moving to use primarily the newer instrument. Because of this predicted transition time, we are including information about both the WAIS-R and the WAIS-III. Additionally, much of the research on the WAIS-R will be directly relevant and applicable to the WAIS-III and is therefore included here.

(i) Standardization and properties of the scale

Similar to the other Wechsler scales discussed, three IQ scores are derived from the WAIS-R subtests. Each of these scores are standard scores with a mean of 100 and a standard deviation of 15, which are created by comparing an individual's score to scores earned by the normative group of the same age. The Verbal IQ is comprised of six verbal subtest scores (Information, Digit Span, Vocabulary, Arithmetic, Comprehension, and Similarities). The Performance IQ is comprised of five nonverbal subtests (Picture Completion, Picture Arrangement, Block Design, Object Assembly, and Digit Symbol). The Full Scale represents the average of the Verbal and Performance IQs.

The WAIS-R was standardized by administering the full scale to 1880 adult subjects, selected according to current US Census data tested between 1976 and 1980. Subjects were stratified according to age, sex, race (white–nonwhite), geographic region, occupation, education, and urban–rural residence. Subjects were divided into nine age groups, corresponding to categories often used by the US Census Bureau. The number in each age group ranged from 160–300, and the age groups spanned from ages 16–74. A problem with the standardization sample noted by Kaufman (1985) was that there was apparent systematic bias in the selection of 16- to 19-year-olds, leading to very questionable teenage norms. Also Hispanics were not included systematically in the total sample. There was no mention of how Hispanics were categorized, if any were tested (Kaufman, 1985).

Reliability coefficients for the 11 tests and the Verbal, Performance, and Full Scale IQs were computed using the split-half method (except for Digit Span and Digit Symbol). Average reliability, across the nine age groups, are as follows: 0.97 for the Verbal IQ; 0.93 for the Performance IQ; and 0.97 for the Full Scale IQ.

Stability coefficients for the three IQs are: 0.97, 0.90, and 0.96 for Verbal, Performance, and Full Scale, respectively.

Many factor analytic studies are available which examine the underlying structure of the WAIS (i.e., *WAIS-R manual,* 1981). Three basic factors have been reported: a "verbal comprehension" factor, a "perceptual organization" factor, and a "memory" factor, which has also been assigned labels like Freedom from Distractibility, Sequential Ability, and Number Ability. These findings are noted to confirm the appropriateness of separating the tests of the WAIS into the Verbal and Performance Scales. Researchers have disagreed about how many factors do underlie the WAIS-R. Some researchers regard the WAIS-R as a one-factor test, stating that the common ability factors account for only a small measure of intellectual ability (O'Grady, 1983). Some have interpreted as many as four or five meaningful WAIS factors for various normal and clinical samples (Cohen, 1957). However, Kaufman (1990) states that there is not any justification for interpreting five WAIS-R factors.

When only two factors are rotated for the WAIS-R, the results do not quite correspond to Wechsler's division of subtests into the Verbal and Performance Scales, although the fit is adequate. In a comparison of six cross-validation samples and the total normative sample using two-factor solutions, all of the Verbal subtests loaded more highly on the Verbal Comprehension than the Perceptual Organization factor (Kaufman, 1990). The loadings from the standardization sample ranged from 0.47 to 0.84 for the Verbal Conceptualization factor, and ranged from 0.45 to 0.72 for the Perceptual Organization factor. Two Verbal tests (Digit Span and Arithmetic) did, however, show strong secondary loadings on the Performance factor. Digit Span and Arithmetic's loadings on the Verbal dimension are also not as consistently strong as the other four Verbal Subtests. Each of the five Performance subtests also consistently loaded more highly on the Perceptual Organization than the Verbal Comprehension factor for the total standardization sample and for the various supplementary groups. Picture Arrangement was the exception, with equal loadings on both factors of the normative group (Kaufman, 1990).

The three-factor solutions for the normal WAIS-R standardization sample demonstrated factors that were fairly well anticipated. Kaufman (1990) discusses the three factor solutions, and presents a table summarizing the data from six samples plus the normative sample (p. 244). The Verbal Comprehension factor was defined by loadings ranging from 0.67 to 0.81, including: Information, Vocabulary, Comprehension, and Similarities. The triad of Picture Completion, Block Design, and Object Assembly comprised the Perceptual Organization factor with loadings in the 0.56–0.73 range. The third factor comprises Digit Span and Arithmetic, with factors of 0.64 and 0.55, respectively. Picture Arrangement and Digit Symbol are more or less unaccounted for in the three-factor solution. Picture Arrangement loads equally on the verbal and nonverbal dimensions. Digit Symbol achieves loadings of only 0.32, 0.38, and 0.36 for each of the factors, loading only marginally on each, but not definitively on any. Depending on the profile obtained by any given individual, examiners may choose to interpret either two or three factors (Kaufman, 1990). The decision to interpret two or three factors should be based on whether the small third dimension is interpretable for a given person.

Studies on gender differences on the WAIS-R have shown that males' earned IQs were higher (although not significantly so) than females' earned IQs (Kaufman, 1990). In a sample of 940 males and 940 females, males scored about two points higher on the VIQ, 1.5 points higher on the PIQ, and two points higher on the FSIQ (Renolds, Chastain, Kaufman, & McLean, 1987). When the gender differences are examined within different age groups, there are larger differences for ages 20–54 than at the extreme age groups of 16–19 and 55–74. For the 20–54 year age range, males scored higher by about 2.5 points on VIQ and PIQ, and by about three points on the FSIQ (Kaufman, 1990).

In examining gender differences on the individual subtests (Kaufman, McLean, & Reynolds, 1988), males and females were found to perform differently on some of the 11 subtests. On Information, Arithmetic, and Block Design males significantly and consistently outperformed females. However, females were far superior on Digit Symbol. On a less consistent basis, males showed superiority on Comprehension, Picture Completion, Picture Arrangement, and Object Assembly. No gender differences for any age group were found for Digit Span, Vocabulary, and Similarities.

Research on WAIS-R profiles has also focused on the area of neuropsychology. In this area it has been hypothesized that lesions in the left cerebral hemisphere are associated with diminished language and verbal abilities, whereas lesions in the right cerebral hemisphere are accompanied by visual–spatial deficits (Reitan, 1955). The hypothesis that has grown from these expected differences is that individuals with left brain lesions will have WAIS-R profiles with $P > V$, and individuals with right hemisphere lesions will have a profile with V > P (Kaufman, 1990). On the basis of numerous WAIS and WAIS-R studies of patients with brain lesions, two general conclusions may be drawn. A summary of empirical data (Kaufman, 1990) leads to a few main conclusions, as follows (see Table 3). First, patients with right hemisphere damage (unilateral or some bilateral damage as well) will most likely demonstrate a V > P profile. Second, patients with left hemisphere, unilateral damage may show a slight P > V profile, but not large enough in size or consistently enough that it is beneficial diagnostically.

A further area of study in subjects with unilateral brain lesions and cognitive ability is with gender differences. Males and females are believed to differ in various aspects of brain functioning. Kaufman (1990) presents data from eight studies that included males and females with brain lesions. The accumulated data are reported to support the alleged gender-related interaction between side of brain lesion and direction of Verbal IQ–Performance IQ difference. Damage to the right hemisphere for both males and females lead to more striking V–P differences than damage to the left hemisphere. However, the V > P of 12 points for males with right lesions is nearly twice the value of 6.5 points for females. For males, the six-point P > V difference for patients with left damage supports the hypothesis of depressed Verbal IQ for left hemisphere lesions. However, the P > V discrepancy of only 1.6 points for females with left hemisphere lesions does not support the reversed hypothesis (Kaufman, 1990). This difference across genders for adults with brain lesions may indicate that women have different cerebral organization than men. However, data supporting the reason for the interaction with gender is not definitive (Kaufman, 1990).

Turkheimer and Farace (1992) performed a meta-analysis of 12 different studies which used Wechsler IQ data to examine both male and female patients with right or left hemisphere damage, including a variety of etiologies. The researchers noted a problem in the previous literature to be the use of the difference between the PIQ and VIQ in measuring the effects of lesions. The V–P differences are determined by potentially separate effects of each hemisphere on the IQs. Thus, in this meta-analysis, separate VIQ and PIQ means were reported for men and women with either right or left hemisphere lesions (Turkheimer & Farace, 1992). The results of the repeated-measures analysis revealed that left hemisphere lesions produce substantial and roughly equal VIQ deficits in male and female patients, but lower mean PIQ scores in female than in male patients. Right hemisphere lesions produce PIQ deficits in both genders, but lower mean VIQ scores in female patients. Mean scores from Turkheimer and Farace's (1992) data are presented in Table 4.

The main effect indicated by the data presented in Table 4 is that "female patients are more sensitive to lesions in the hemisphere

Table 3 Effects of unilateral brain damage on WAIS/WAIS-R VIQ–PIQ discrepancies.

Group	*Sample size*	*Mean VIQ minus mean PIQ*	
		Left damage	*Right damage*
Stroke			
Men	124	−10.1	+16.8
Women	81	+0.1	+9.5
Total	248	−6.4	+13.5
Tumor (generalized or posterior)	200	+0.2	+8.4
Frontal lobe	104	−2.2	+2.6
Temporal lobe epilepsy			
Preoperative	101	−3.1	+2.4
Postoperative	101	−6.4	+6.0
Acute lesion	109	−2.4	+14.2
Chronic lesion	131	−2.5	+5.5
Age 20–34	664	−5.0	+6.7
Age 35–54	1245	−3.9	+9.5
Age 55+	168	−2.9	+14.9
Whites	50	−5.2	+15.1
Blacks	50	+5.7	+10.4

Total sample size = 983.

opposite to that thought to be 'odominant' for a function" (Turkheimer & Farace, 1992, p. 499). Although these results are consistent with previously reported greater V–P differences in males, the analysis show that there is also no difference between male and female patients in the effects of left hemisphere lesions on VIQ, or right hemisphere lesions on PIQ. The females demonstrated a pattern of lower mean scores following lesions to hemisphere opposite to the "dominant" hemisphere for each function. This pattern is supportive of a model which asserts that there is a greater degree of bilateral processing in women (Turkheimer & Farace, 1992). This gender difference could be the result of many things including: degree of hemispheric lateralization, differences in problem-solving strategy, or callosal function.

According to Turkheimer, Farace, Yfo, and Bigler (1993), two major findings have been suggested by earlier studies. Individuals with lesions in the left hemisphere have smaller Verbal IQ–Performance IQ differences than subjects with lesions in the right hemisphere, and this difference is greater for males than females. Theories of why gender differences exist can be evaluated through the lesion data. The degree of lateralization in males and females cannot account for gender differences in PIQ and VIQ, because a "statistical model in which the genders have the same degree of lateralization fits the data as well as a model in which the genders are allowed to differ" (Turkheimer et al., 1993, p. 471). There was also not support for the hypothesis that the gender difference results from differences in the within-hemisphere organization of verbal skills.

In a study examining 64 patients through archival data, Turkheimer et al. (1993) did find Inglis and Lawson's (1982) hypothesis that females use verbal strategies in solving PIQ items to be supported by their data. In females, a single model of lesion effects could account for deficits in VIQ and PIQ, but this was not found for males. The most striking observation made was that females with left-hemisphere lesions had substantial deficits in PIQ related to lesion parameters, but males with left-hemisphere lesions did not (Turkheimer, 1993). Notably, this difference could be present because in the left-hemisphere females may have more nonverbal abilities relevant to PIQ, or females may use more verbal strategies in solving PIQ items. Further research examining problem-solving strategy is necessary to clarify the reason for these gender differences.

(ii) Overview

The WAIS-R has proven itself as a leader in the field of adult assessment. Kaufman (1985) stated, "The WAIS-R is *the* criterion of adult intelligence, and no other instrument is even close." Matarazzo (1985) had an equally favorable review of the WAIS-R, applauding its strong psychometric qualities and clinical usefulness. It has strong reliability and validity for Verbal, Performance, and Full Scale IQs, as did its predecessor, the WAIS. The separate subtests, however, have split-half reliability coefficients that are below 0.75 for six of the 11 tasks at ages 16–17, and for tasks across the age range (Picture Arrangement and Object Assembly) (Kaufman, 1985). The sample selection included apparent systematic bias in the selection of individuals ages 16–19, leading to very questionable teenage norms (Kaufman, 1985). However, the rest of the sample selection was done with precision, leading to an overall well-stratified sample.

Administration is not difficult with the clear and easy to read WAIS-R manual, which provides good scoring directions (Spruill, 1984). The administration and scoring rules of the WAIS-R were made more uniform with the WISC-R rules, which facilitates transfer (Kaufman, 1985). In addition, for the Verbal items with subjective scoring systems, the scoring criteria has been expanded to reduce ambiguity; and to facilitate administration, all words spoken by the examiner are placed on separate lines of the administration manual (Kaufman, 1985).

The WAIS-R does have its limitations; some of which are the nonuniformity of the scaled scores, and the limited floor and ceiling (Spruill, 1984). Individuals who are extremely gifted or severely retarded cannot be assessed adequately with the WAIS-R because the range of possible Full Scale IQ scores is only 45–150. Several subtests have insufficient floors for adequate assessment of retarded individuals: Picture Arrangement, Arithmetic, Similarities, Picture Completion, and Block Design (Kaufman, 1985). If evaluating an individual who falls at the extreme low end, this is a distinct disadvantage. In addition, even if a subject receives a raw score of zero on a subtest, they can receive one scaled-score point on that subtest.

The WAIS's method of using a reference group (ages 20–34) to determine everyone's scaled scores was retained in the development of the WAIS-R. Kaufman (1985) stated that this method is "indefensible," because use of this single reference group impairs profile interpretation below age 20 and above 34. Profile interpretation is further impaired for individuals aged 16–17 because of low subtest reliability. The WAIS and WAIS-R studies at ages 35–44 cannot be generalized to individuals aged 16–19 because of poor teenage norms, again negatively impacting a clinician's ability to interpret the profile. In the WAIS-R appendix, clinicians must utilize separate scaled-score tables which are arranged by age group. These separate tables invite clerical errors and confusion in case reports (Kaufman, 1985). The WAIS-R manual itself fails to provide appropriate empirical guidelines for profile interpretation, showing a limited awareness of clinicians' practical needs (Kaufman, 1985). However, despite these limitations, the WAIS-R is still one of the most readily chosen instruments in the assessment of intelligence.

4.08.2.1.5 *Wechsler Adult Intelligence Scale-Third Edition (WAIS-III)*

(i) Description

The newest member of the Wechsler family of tests is the WAIS-III (The Psychological Corporation, 1997). The WAIS-III is an instrument for assessing the intellectual ability of individuals aged 16–89. Like the other Wechsler scales discussed, three IQ scores (Verbal, Performance, and Full Scale) and four factor indices (Verbal Comprehension, Perceptual Organization, Working Memory, and Processing Speed) are derived from the WAIS-III subtests. Each of these scores are standard scores with a mean of 100 and a standard deviation of 15, which are created by comparing an individual's score to scores earned by the normative group of the same age. The Verbal IQ is comprised of six verbal subtest scores (Vocabulary, Similarities, Arithmetic, Digit Span, Information, and Comprehension), plus a new supplementary test to substitute for Digit Span if necessary (Letter–Number Sequencing). The Performance IQ is comprised of five nonverbal subtests (Picture Completion, Picture Arrangement, Block Design, Matrix Reasoning, and the renamed Digit Symbol-Coding). In addition, two supplemental subtests are provided on the Performance scale: Symbol Search (which may be used to replace Digit Symbol-Coding) and Object Assembly (which is an optional subtest that may be used to replace any performance subtest for individuals younger than 75). In addition to its new name, Digit Symbol-Coding also has two new optional procedures not used in IQ computation, which may be used to help the examiner rule out potential problems. These new procedures include Digit Symbol-Incidental Learning and Digit Symbol-Copy. The Full Scale represents the average of the Verbal and Performance IQs.

New to the WAIS-III are additional factor indices, which can be helpful in further breaking down and understanding an individual's performance. Like the WISC-III, there are four factor indices: Verbal Comprehension, Perceptual Organization, Working Memory, and Processing Speed. The two new subtests on the WAIS-III, Letter–Number Sequencing and Symbol Search, are used in calculation of the Working Memory and Processing Speed Indices, respective. Table 5 shows which tests comprise each of the IQs and factor indices.

(ii) Standardization properties of the scale

The WAIS-III was standardized by administering the full scale to 2450 adult subjects, selected according to 1995 US Census data. Subjects were stratified according to age, sex, race/ethnicity, geographic region, and education level. Subjects were divided into 13 age groups, which is an improvement over the nine age groups tested in the WAIS-R standardization sample. The number in each WAIS-III standardization age group ranged from 100 to 200, and the age groups spanned from age 16 to 89. Due to the fact that US citizens are living longer, the WAIS-III developers extended norms beyond the highest age group (74) provided in the WAIS-R. In the collection of normative data, an additional 200 African American and Hispanic individuals were also administered the WAIS-III without discontinue rules. "This over sampling provided a sufficient number of item scores across all items for item bias analyses" (The Psychological Corporation, 1997, p. 20).

Reliability coefficients for the 14 subtests and the Verbal, Performance, and Full Scale IQs were computed using the split-half method (except for Digit Symbol-Coding and Symbol Search). Average reliability, across the 13 age

Table 5 Subtests comprising WAIS-III IQs and Index Scores.

Subtest	*IQ scale*		*Factor index*			
Vocabulary	VIQ		VCI			
Similarities	VIQ		VCI			
Information	VIQ		VCI			
Comprehension	VIQ					
Arithmetic	VIQ				WMI	
Digit Span	VIQ				WMI	
Letter–number Sequencing[a]					WMI	
Picture Arrangement		PIQ				
Picture Completion		PIQ		POI		
Block Design		PIQ		POI		
Matrix Reasoning		PIQ		POI		
Digit Symbol-coding		PIQ				PSI
Symbol Search[a]						PSI
Object Assembly[a]						

Note. Verbal IQ (VIQ); Performance IQ (PIQ); Verbal Comprehension Index (VCI); Perceptual Organization Index (POI); Working Memory Index (WMI); Processing Speed Index (PSI).

[a] The Letter–Number Sequencing, Symbol Search, and Object Assembly subtests can substitute for other subtests under certain circumstances (see The Psychological Corporation, 1997).

groups, is as follows: 0.97 for the Verbal IQ; 0.94 for the Performance IQ; and 0.98 for the Full Scale IQ. The average individual subtests' reliabilities ranged from 0.93 (Vocabulary) to 0.70 (Object Assembly), with a median coefficient of 0.85. Stability coefficients for the three IQs are: 0.96, 0.91, and 0.96 for Verbal, Performance, and Full Scale, respectively. The stability coefficients for individual subtests ranged from an average of 0.94 (Information) to 0.69 (Picture Arrangement) with a median coefficient of 81.5.

The WAIS-III manual (The Psychological Corporation, 1997) reports that numerous factor analytic studies (exploratory and confirmatory) examined the underlying structure of the WAIS-III. There were four basic factors predicted to be underlying the WAIS-III: Verbal Comprehension, Perceptual Organization, Working Memory, and Processing Speed. Overall, results of exploratory and confirmatory factor analysis support the appropriateness of separating the tests of the WAIS into the four factors. The manual reports that the four factor model is a "clearly superior solution to a one-, two-, or three-factor solution and more parsimonious than a five-factor one" (p. 110). Except for the oldest age group, the findings across all ages are similar. However, in the 75–89 year age range, many more subtests loaded on the Processing Speed factor than the Perceptual Organization Factor (i.e., Block Design, Picture Completion, and Picture Arrangement all load on Processing Speed). Only Matrix Analogies had a factor loading above 0.40 on the Perceptual Organization factor for the oldest age group. From the data presented with the standardization sample, it appears that the WAIS-III is best represented by the four factors that were originally predicted to underlie it.

Across all ages, the Verbal Comprehension factor was defined by loadings ranging from 0.76 to 0.89, including: Information, Vocabulary, Comprehension, and Similarities. Picture Completion, Block Design, Matrix Reasoning, and Picture Arrangement comprised the Perceptual Organization factor with loadings in the 0.47–0.71 range. The third factor is comprised of Digit Span, Arithmetic, and Letter–Number Sequencing with factor loadings of 0.71, 0.51, and 0.62, respectively. Symbol Search and Digit Symbol-Coding are assumed in the Processing Speed factor, with loadings of 0.63 and 0.68, respectively. The Symbol Search subtest requires the examinee to determine whether a pair of target symbols are present in a larger group of shapes within a specified time limit. The addition of the new subtests seems to have strengthened the factor structure, as in the previous version of the WAIS, some of the subtests did not load strongly on any of the factors or loaded similarly across the factors (i.e., Picture Arrangement and Digit Symbol).

(iii) Preliminary research with the WAIS-III

The WAIS-R and the WAIS-III were compared to see how well they were related (The Psychological Corporation, 1997). A sample of 192 individuals with a mean age of 43.5 years (ranging from 16 to 74) were administered the two tests. The median time between administrations was 4.7 weeks. As would be predicted by work done by Flynn (1984), subjects scored 2.9 points lower on the WAIS-III FSIQ than on the WAIS-R FSIQ. The WAIS-III VIQ and PIQ were 1.2 points and 4.8 points lower than the respective WAIS-R scales. The overall correlations between the WAIS-III and WAIS-R global scales were high. The correlation coefficients for the VIQ, PIQ, and FSIQ were 0.94, 0.86, and 0.93, respectively.

The WAIS-III and WISC-III were also administered to a sample of adolescents to determine how well the two tests correlated (The Psychological Corporation, 1997). The sample consisted of 184 16-year olds who were administered the two tests from 2 to 12 weeks apart (median time = 4.6 weeks). The correlations between the global scales of the two tests were very high, indicating that the two instruments appear to be measuring very similar constructs. The VIQ, PIQ, and FSIQ correlation coefficients were 0.88, 0.78, and 0.88, respectively. The Index scores from the WAIS-III and WISC-III were also compared. The Indices' correlations were 0.87, 0.74, 0.80, and 0.79 for the VCI, POI, WMI, and PSI, respectively. The differences between the mean WISC-III and WAIS-III IQs were all less than one point. The differences between the two tests' mean VCI and POI were also each less than one point. The difference between the WAIS-III and WISC-III mean WMI was 1.7 standard score points. On the PSI, the difference between the means on the two tests was 2.7 points. Thus, overall, the IQ and Indices of the two tests correspond quite highly.

The WAIS-III Technical Manual (The Psychological Corporation, 1997) also presents some studies collected from clinical groups with neurological, psychiatric, and developmental disorders. Reviewed here are a select group of these studies, including those from a sample of patients with mild Alzheimer's disease, a sample of individuals who are mentally retarded, and one from individuals with attention-deficit hyperactivity disorder (ADHD).

Individuals with probable Alzheimer's disease ($N = 35$) were administered both the WAIS-III and the Wechsler Memory Scales-Third Edition (WMS-III). Decrements in cognitive ability and memory were predicted. This sample was reported to have a significantly higher level of education than the normal population, with 48.6% of the sample having completed at least four years of college. The results of this study (The Psychological Corporation, 1997) show that the individuals with probable Alzheimer's disease had lower scores on all IQ scales than the general population. The mean VIQ, PIQ, and FSIQ scores were 92.2, 81.7, and 86.6, respectively. The PIQ scores tend to be more sensitive to the effects of this neurological condition; thus, the mean VIQ score is predictably higher than the PIQ score. The mean factor index scores demonstrate more differentiation in their cognitive profile. This sample had a mean factor indices of 79.6 (PSI), 84.8 (POI), 87.2 (WMI), and 93.0 (VCI).

A total of 108 individuals diagnosed with mental retardation were administered the WAIS-III. Six of these, 46 were categorized as having mild mental retardation, while the other 62 had moderate mental retardation (The Psychological Corporation, 1997). The results demonstrated deficits across all areas of cognitive functioning, as expected. In the mildly mentally retarded group, mean IQ scores were as follows: 60.1 (VIQ), 64.0 (PIQ), and 58.3 (FSIQ). The subjects with moderate mental retardation exhibited lower scores, earning mean VIQ, PIQ, and FSIQ scores of 54.7, 55.3, and 50.9, respectively. The variability in scores of each of these clinical groups is much smaller than found in the general population. The standard deviations are more than 50% smaller than those found in the general population.

ADHD sufferers was another group studied and reported in the WAIS-III technical manual (The Psychological Corporation, 1997). Traditionally, IQ scores have not be useful in discriminating ADHD from non-ADHD individuals. However, examining subtests patterns on tests of cognitive ability has been more fruitful in discriminating those with ADHD from those without.

The WAIS-III was administered to 30 individuals diagnosed with ADHD (mean age 19.8 years). The mean level of intellectual functioning was found to be in the Average range for this group (mean FSIQ = 103.00). In addition, there was no significant difference found between Verbal and Performance IQs for the group (104.2 and 100.9, respectively). The WAIS-III factor indices were also examined, and the pattern of performance on the indices was found to differ in comparison to the general population. The ADHD sample scored on average 8.3 points lower on the WMI than the VCI. About 30% of the ADHD sample had WMI scores at least 1 SD lower than their VCI scores, whereas 13% of the WAIS-III standardization sample had obtained discrepancies of this magnitude. On average, the ADHD sample scored 7.5 points lower on the PSI than the POI. In the ADHD sample, 26% of the group had PSI scores at least 1 SD lower than their POI scores, but only 14% of the WAIS-III standardization sample had such discrepancies.

(iv) Analyzing the WAIS-III data

The WAIS-III manual provides a general description of how a clinician may begin to interpret the plethora of data obtained in its 14 subtests. However, to obtain the maximum amount of information from the profile, one should utilize an approach to profile interpretation that will group and regroup subtests (Kaufman & Lichtenberger, in press). Similar to the WISC-III interpretation, the WAIS-III may be examined from the global level (IQs) to the individual profile (subtest) level. An organized, systematic approach will be advantageous in obtaining the most accurate picture of the individual.

The WAIS-III record form provides a nice beginning to profile interpretation. However, a structure is needed to work through the large amount of data in a systematic fashion. Kaufman and Lichtenberger, (in press) have developed a series of 10 steps to aid the clinician in interpreting and integrating all of the data obtained from the WAIS-III's three IQs and four factor indices, while not becoming overwhelmed with the multiple scores and difference scores. The 10 steps, a step-by-step approach to WAIS-III profile interpretation, is presented in summary form below. The 10 steps are presented in Table 6. Using these 10 steps can help to organize the information to generate meaningful hypotheses about personal cognitive strengths and weaknesses in preparation for clear presentation in the form of a written report.

(v) Overview

WAIS-III is likely to follow in its footsteps of the WAIS-R, which has proven itself as a leader in the field of adult assessment. The new norms and psychometric improvements of the WAIS-III are much welcomed by the assessment community. The WAIS-III has strong reliability and validity for Verbal, Performance, and Full Scale IQs, as did its predecessor, the WAIS-R. The subtest with the lowest split half reliability has been removed from the computation of the IQs (Object Assembly). However, Picture Arrangement still exhibits split half reliability coefficients below 0.75 at several ages, and it remains part of the Performance IQ. The WAIS-III sample selection was done with precision, leading to an overall well-stratified sample.

Many visual and practical improvements were made in the development of the WAIS-III. Administration is not difficult with the clear and easy to read WAIS-III manual, in addition to the record form with ample space and visual icons (Kaufman & Lichtenberger, in press). The administration and scoring rules of the WAIS-III were made more uniform throughout the entire test, which reduces chances of examiner error. In addition, the scoring rules are listed right in the administration manual for the Verbal items with subjective scoring systems. This change from the WAIS-R has eased the work of clinicians (no more flipping back and forth during administration).

The WAIS-III attempted to improve its floor and ceiling in comparison to the earlier version. Several step-down items have been added on each subtest for lower functioning individuals. However, like the WAIS-R, individuals who are extremely gifted or severely retarded cannot be adequately assessed with the WAIS-III because the range of possible Full Scale IQ scores is only 45–150. Studies on individuals in the lower extreme range of the WAIS-III are yet to determine whether evaluating an individual who falls at the extreme low end is a distinct disadvantage. As on the WAIS-R, even if a subject receives a raw score of zero on a subtest, they can receive one to five scaled-score points on that subtest. Uniformity is not found across the range of scaled scores for each subtest. On certain subtests subjects may reach a ceiling more quickly than on others. At certain ages, ordinarily the highest scaled score that can be obtained on the subtest is 19; however, on the Arithmetic or Picture Arrangement subtest, 17 is the maximum score (Kaufman & Lichtenberger, in press). Profile analysis is made difficult because of this nonuniformity across subtests, especially for the extremely gifted subjects.

The method of the WAIS-R of using a reference group (ages 20–34) to determine everyone's scaled scores was not retained in the development of the WAIS-III. Kaufman (1985) stated that this WAIS-R method is "indefensible," because use of this single reference group impairs profile interpretation below age 20 and above 34; thus, the WAIS-III change in determining scaled scores is a significant improvement. The process of profile interpretation has been made much less confusing by the removal of the reference group scores. (However, if one wants to calculate the scores by using the 20–34 reference group, this is still possible.) Fewer clerical errors and less confusion in case reports will be present because of these changes (Kaufman & Lichtenberger, in press). The WAIS-III manual and record form themselves provide the beginning to interpretation, with clearly laid out tables to calculate score discrepancies, and so forth. However, to meet clinicians' practical needs for more specific empirical guidelines for profile interpretation in a systematic and step-by-step fashion, other

Table 6 Ten tips for WAIS-III interpretation.

Step 1. Interpret the Full Scale IQ.
(i) Report the FSIQ confidence interval (The Psychological Corporation, 1997; Table A.5 p. 197).
(ii) Report the FSIQ percentile rank (The Psychological Corporation, 1997; Table A.5 p. 197).
(iii) Report the FSIQ ability level (The Psychological Corporation, 1997, Table 2.3 p. 25).
(iv) If in STEPS 2–6, it is determined that there is a significant difference between the component parts of the FSIQ (i.e., VIQ & PIQ or VCI & POI), the FSIQ should not be interpreted as a meaningful representation of the individual's overall performance.

Step 2. Determine if the Verbal–Performance IQ discrepancy is statistically significant.
(i) For all ages VIQ–PIQ difference of *6 points* is significant at *0.15 level.*
(ii) For all ages VIQ–PIQ difference of *9 points* is significant at *0.05 level.*
(iii) Values for specific ages are presented in Table B.1 (The Psychological Corporation, 1997; p. 205).

Step 3. Determine if the VIQ and PIQ are interpretable. Four questions to consider about the Verbal and Performance Scales.

Verbal Scale
(i) Is the difference between VCI and WMI statistically significant ($p < 0.05$)?
Size needed for difference = *10+ points.*
(ii) Is there abnormal scatter among the VIQ subtests?
Highest of 6 VIQ subtest scaled scores minus lowest = *8+ points.*

Performance Scale
(iii) Is the difference between POI and PSI statistically significant ($p < 0.05$)?
Size needed for difference = *13+ points.*
(iv) Is there abnormal scatter among the PIQ subtests?
Highest of 5 PIQ subtest scaled scores minus lowest = *8+ points.*

Step 4. Determine if VIQ–PIQ discrepancy is interpretable or if the VCI and POI should be interpreted instead.
(i) If all answers in Step 3 are *no*, then the VIQ–PIQ discrepancy is interpretable. Skip Step 5 and go directly to Step 6.
(ii) If the answer to one or more of the questions in Step 3 is *yes*, then the VIQ–PIQ discrepancy may not be interpretable.
(iii) If VIQ–PIQ is not interpretable, then examine the VCI–POI discrepancy in Step 5.

Step 5. Determine whether VCI and POI are interpretable and significantly different from one another.
(i) Is there abnormal scatter among the VCI subtests?
Highest of 3 VCI subtest scaled scores minus lowest = *5+ points.*
(ii) Is there abnormal scatter among the POI subtests?
Highest of 3 POI subtest scaled scores minus lowest = *6+ points.*
(iii) If the answer to either (i) or (ii) is yes, then VCI–POI difference may not be interpretable. Otherwise, if both answers are no, examine the interpretable VCI–POI difference:
    (a) Is the difference between VCI and POI statistically significant ($p < 0.05$)?
    (b) Size needed for difference = *10+ points.*

Step 6. Determine if the VIQ–PIQ discrepancy (or the VCI–POI discrepancy) is abnormally large.
(i) *17 Point* difference is abnormally large for the VIQ–PIQ.
(ii) *19 Point* difference is abnormally large for the VCI–POI.
(iii) Exact point values according to ability level are available in Appendix D (The Psychological Corporation, 1997, pp. 300–309)
(iv) If the discrepancies are abnormally large, this indicates that they are too big to ignore (see Steps 4 & 5), and they may be interpreted anyway.

Step 7. Determine whether the Working Memory and Processing Speed indices are interpretable.
(i) Do not interpret WMI if scatter among the 3 subtests is = *6+ points.*
(ii) Do not interpret PSI if difference among 2 subtests is = *4+ points.*

Step 8. Interpret the Global Verbal and Nonverbal Dimensions, as well as the small factors, if they were found to be interpretable.
Study the information and procedures presented in (Kaufman & Lichtenberger, in press).

Step 9. Interpret significant strengths and weaknesses in the WAIS-III subtest profile.
(i) If the VIQ–PIQ discrepancy is less than 17 points, use the individual's mean of all WAIS-III subtests as the person's midpoint.
(ii) I the VIQ–PIQ discrepancy is 17 or more points, use 2 separate means:
    (a) Use the individual's mean of all the Verbal subtests as the midpoint for determining strengths and weaknesses on Verbal subtests;

Table 6 (continued)

(b) Use the individual's mean of all the Performance subtests as the midpoint for determining strengths and weaknesses on Performance subtests.

(iii) Subtract the individual's mean from each of the subtest scaled scores to determine strengths and weaknesses. Round to the nearest whole number.

(iv) Values are presented in Table B.3 (The Psychological Corporation, 1997, p. 208) for determining if a subtest significantly deviates from the individual's own mean. The following summary information may also be used to determine significance:

±2 points: Vocabulary
±3 points: Similarities, Arithmetic, Digit Span, Information, Comprehension, Coding, Block Design, Matrix Reasoning,
±4 points: Letter-Number Sequencing, Picture Completion, Picture Arrangement, Symbol Search
±5 points: Object Assembly.

Step 10. Generate hypotheses about the fluctuations in the WAIS-III subtest profile.

Review the information presented in Kaufman and Lichtenberger (in press) which detail how to reorganize subtest profiles to systematically generate hypotheses about strengths and weaknesses.

---

sources are available (Kaufman & Lichtenberger, in press). Undoubtedly, like its predecessors, the WAIS-III is likely to become one of the most readily chosen instruments in the assessment of intelligence.

4.08.2.1.6 Kaufman Assessment Battery for Children (K-ABC)

The K-ABC is a battery of tests measuring intelligence and achievement of normal and exceptional children aged 2.5–12.5. It yields four scales: Sequential Processing, Simultaneous Processing, Mental Processing Composite (Sequential and Simultaneous), and Achievement.

The K-ABC is becoming a frequently used test in intelligence and achievement assessment that is used by both clinical and school psychologists (Kamphaus, Beres, Kaufman, & Kaufman, 1995). In a nationwide survey of school psychologists conducted in 1987 by Obringer (1988), respondents were asked to rank the following instruments in order of their usage: Wechsler's scales, the K-ABC, and both the old and new Stanford–Binets. The Wechsler scales earned a mean rank of 2.69, followed closely by the K-ABC with a mean of 2.55, the L-M version of the Binet (1.98), and the Stanford–Binet Fourth Edition (1.26). Bracken (1985) also found similar results of the K-ABC's popularity. Bracken surveyed school psychologists and found that for ages 5–11 years the WISC-R was endorsed by 82%, the K-ABC by 57%, and the Binet IV by 39% of the practitioners. These results suggest that clinicians working with children should have some familiarity with the K-ABC (Kamphaus et al., 1995).

The K-ABC has been the subject of great controversy from the outset, as evident in the strongly pro and con articles written for a special issue of the *Journal of Special Education* devoted to the K-ABC (Miller & Reynolds, 1984). Many of the controversies, especially those regarding the validity of the K-ABC theory, will likely endure unresolved for some time (Kamphaus et al., 1995). Fortunately, the apparent controversy linked to the K-ABC has resulted in numerous research studies and papers that provide more insight into the K-ABC and its strengths and weaknesses.

(i) Theory

The K-ABC intelligence scales are based on a theoretical framework of Sequential and Simultaneous information processing, which relates to how children solve problems rather than what type of problems they must solve (e.g., verbal or nonverbal). In stark contrast is Wechsler's theoretical framework of the assessment of "g," a conception of intelligence as an overall global entity. As a result, Wechsler used the Verbal and Performance scales as a means to an end. That end is the assessment of general intelligence. In comparison, the Kaufmans emphasize the individual importance of the Sequential and Simultaneous scales in interpretation, rather than the overall Mental Processing Composite (MPC) score (Kamphaus et al., 1995).

The Sequential and Simultaneous framework for the K-ABC stems from an updated version of a variety of theories (Kamphaus et al., 1995). The foundation lies in a wealth of research in clinical and experimental neuropsychology and cognitive psychology. The Sequential and Simultaneous theory was primarily developed from two lines of theory: the information processing approach of Luria (e.g., Luria, 1966), and the cerebral specialization work of Sperry (1968, 1974), Bogen (1969), Kinsbourne (1975), and Wada, Clarke, and Hamm (1975).

The neuropsychological processing model, which originated with the neurophysiological observations of Luria (1966, 1973, 1980) and Sperry (1968), the psychoeducational research of Das (1973; Das et al., 1975; Das, Kirby, & Jarman, 1979; Naglieri & Das, 1988, 1990), and the psychometric research of Kaufman and Kaufman (1983), possesses several strengths relative to previous models in that it (i) provides a unified framework for interpreting a wide range of important individual difference variables; (ii) rests on a well-researched theoretical base in clinical neuropsychology and psychobiology; (iii) presents a processing, rather than a product-oriented, explanation for behavior; and (iv) lends itself readily to remedial strategies based on relatively uncomplicated assessment procedures (Kaufman & Kaufman, 1983; McCallum & Merritt, 1983; Perlman, 1986).

This neuropsychological processing model describes two very distinct types of processes which individuals use to organize and process information received in order to solve problems successfully: successive or sequential, analytic-linear processing vs. holistic/simultaneous processing (Levy & Trevarthen, 1976; Luria, 1966). These processes have been identified by numerous researchers in diverse areas of neuropsychology and cognitive psychology (Perlman, 1986). From Sperry's cerebral specialization perspective, these processes represent the problem-solving strategies of the left hemisphere (analytic/sequential) and the right hemisphere (Gestalt/holistic). From Luria's theoretical approach, successive and simultaneous processes reflect the "coding" processes that characterize "Block 2" functions.

Regardless of the theoretical model, successive processing refers to the processing of information in a sequential, serial order. The essential nature of this mode of processing is that the system is not totally surveyable at any point in time. Simultaneous processing refers to the synthesis of separate elements into groups. The essential nature of this mode of processing is that any portion of the result is, at once, surveyable without dependence on its position in the whole. The model assumes that the two modes of processing information are available to the individual. The selection of either or both modes of processing depends on two conditions: (i) the individual's habitual mode of processing information as determined by social–cultural and genetic factors, and (ii) the demands of the task (Das et al., 1975).

In reference to the K-ABC, Simultaneous processing refers to the mental ability to integrate information all at once to solve a problem correctly. Simultaneous processing frequently involves spatial, analogic, or organizational abilities (Kaufman & Kaufman, 1983; Kamphaus & Reynolds, 1987). There is often a visual aspect to the problem and visual imagery used to solve it. A prototypical example of a Simultaneous subtest is the Triangles subtest on the K-ABC, which is similar to Wechsler's Block Design. To solve both of these subtests, children must be able to see the whole picture in their mind and then integrate the individual pieces to create the whole.

In comparison, Sequential processing emphasizes the ability to place or arrange stimuli in sequential or serial order. The stimuli are all linearly or temporally related to one another, creating a form of serial interdependence within the stimulus (Kaufman & Kaufman, 1983). The K-ABC subtests assess the child's Sequential processing abilities in a variety of modes. For example, Hand Movements involves visual input and a motor response, Number Recall involves auditory input with a vocal response, and Word Order involves auditory input and visual response. These different modes of input and output allow the examiner to assess the child's sequential abilities in a variety of ways. The Sequential subtests also provide information on the child's short-term memory and attentional abilities.

According to Kamphaus et al. (1995), one of the controversial aspects of the K-ABC was the fact that it took the equivalent of Wechsler's Verbal Scale and redefined it as "achievement." The Kaufmans' analogs of tests such as Information (Faces & Places), Vocabulary (Riddles and Expressive Vocabulary), and Arithmetic (Arithmetic) are included on the K-ABC as achievement tests and viewed as tasks that are united by the demands they place on children to extract and assimilate information from their cultural and school environment. The K-ABC is predicated on the distinction between problem solving and knowledge of facts. The former set of skills are interpreted as intelligence; the latter is defined as achievement. This definition presents a break from other intelligence tests, where a person's acquired factual information and applied skills influence greatly the obtained IQ (Kaufman & Kaufman, 1983).

(ii) Standardization and properties of the scale

Stratification of the K-ABC standardization sample closely matched the 1980 US Census data on the variables of age, gender, geographic region, community size, socioeconomic status (SES), race or ethnic group, and parental occupation and education. Additionally, unlike most other intelligence measures for children, stratification variables also included educational placement of the child (see Table 7).

Table 7 Representation of the K-ABC standardization sample by educational placement.[a]

Educational placement	*N*	*%*	*%*
Regular classroom	1862	93.1	91.1
Speech impaired	28	1.4	2.0
Learning disabled	23	1.2	2.3
Mentally retarded	37	1.8	1.7
Emotionally disturbed	5	0.2	0.3
Other[b]	15	0.8	0.7
Gifted and talented	30	1.5	1.9[c]
Total K-ABC sample	2000	100.0	100.0

[a] Data from US Department of Education, National Center for Education Statistics. 1980. Table 2.7, The Condition of Education, Washington, DC, US Government Printing Office. [b] Includes other health impaired, orthopedically handicapped, and hard of hearing. [c] Data from US Office for Civil Rights, 1980, *State, Regional, and National Summaries of Data from the 1978 Child Rights Survey of Elementary and Secondary Schools* (p. 5). Alexandria, VA: Killalea Associates.

Reliability and validity data provide considerable support for the psychometric aspects of the test. A test–retest reliability study was conducted with 246 children after a two- to four-week interval (mean interval = 17 days). The coefficients for the Mental Processing Composite were 0.83 for age two years, six months through four years, eleven months; 0.88 for ages five years through eight years, eleven months; and 0.93 for ages nine years to 12 years, five months. Test–retest reliabilities for the Achievement scale composite for the same age groups were 0.95, 0.95, and 0.97, respectively (Kamphaus et al., 1995). The test–retest reliability research reveals that there is a clear developmental trend, with coefficients for the preschool ages being smaller than those for the school-age range. This trend is consistent with the known variability over time that characterizes preschool children's standardization test performance in general (Kamphaus & Reynolds, 1987). Split-half reliability coefficients for the K-ABC global scales range from 0.86 to 0.93 (mean = 0.90) for preschool children, and from 0.89 to 0.97 (mean = 0.93) for children aged 5–12.5 (Kamphaus et al., 1995).

There has been a considerable amount of research done on the validity of the K-ABC. The *K-ABC interpretive manual* (Kaufman & Kaufman, 1983) includes the results of 43 such studies. Construct validity was established by looking at five separate topics: developmental changes, internal consistency, factor analysis (principal factor, principal components, and confirmatory), convergent and discriminant analysis, and correlations with other tests. Factor analysis of the Mental Processing Scales offered clear empirical support for the existence of two, and only two, factors at each age level, and for the placement of each preschool and school-age subtest on its respective scale. Analyses of the combined processing and achievement subtests also offered good construct validation of the K-ABC's three-scale structure (Kaufman & Kamphaus, 1984).

Although the K-ABC and the WISC-III differ from one another in a number of ways, there is strong evidence that the two measures correlate substantially (Kamphaus & Reynolds, 1987). In a study of 182 children enrolled in regular classrooms, the Mental Processing Composite (MPC) correlated 0.70 with WISC-R Full Scale IQ (FSIQ), thus, sharing a 49% overlap in variance (Kamphaus et al., 1995; Kaufman & Kaufman, 1983). There have also been numerous correlational studies conducted with handicapped and exceptional populations that may be found in the *Interpretative manual*. The overall correlation between the K-ABC and the WISC-R range from 0.57 to 0.74, indicating that the two tests overlap a good deal, yet also show some independence (Kamphaus et al.).

(iii) Overview

Although the K-ABC has been the subject of past controversy, it appears that it has held its own and is used often by professionals. The K-ABC is well designed with easy to use easels and manuals. The information in the manuals is presented in a straightforward, clear fashion, making use and interpretation of the K-ABC relatively easy (Merz, 1985). There has been a considerable amount of research done on the validity of the K-ABC and the authors have done a thorough job of presenting much of that information in the manual. The reporting of the reliability and validity data in the manual is complete and understandable. However, there is not enough information presented on the content validity of the test. The various tasks on the subtests on the K-ABC are based on clinical, neuropsychological, and/or other research-based validity; however, a much clearer explication of the rationale behind some of the novel subtests would have been quite helpful (Merz, 1985).

The K-ABC measures intelligence from a strong theoretical and research basis, evident in the quality of investigation in the amount of research data presented in the manual (Merz, 1985). The K-ABC was designed to measure the intelligence and achievement of children aged 2.5–12.5 and the research done to date suggests that in fact the test does just that. The Nonverbal Scale significantly contributes to the effort to addressing the diverse needs of minority groups and language handicapped children. Overall, it appears that the authors of the K-ABC have met the goals listed in the interpretative manual and that this battery is a valuable assessment tool (Merz, 1985).

Keith and Dunbar (1984) present an alternate means of interpreting the K-ABC, based on exploratory and confirmatory factor analytic data. The two K-ABC Reading subtests are eliminated in their alternate analysis, and factors labeled Verbal Memory, Nonverbal Reasoning, and Verbal Reasoning are presented. For school-aged children whose Achievement Scale splits in half, this model may help interpret their profile. A problem with the Keith and Dunbar labels is that they do not offer evidence to support their Verbal Memory and Nonverbal Reasoning labels. Keith and Dunbar conclude that considerable caution be used when interpreting K-ABC results. In the K-ABC Interpretive Manual (Kaufman & Kaufman, 1983), it is also stressed that a child's profile may need to be approached from an alternative model, if the author's model does not create a good interpretation of the profile.

4.08.2.1.7 Kaufman Adolescent and Adult Intelligence Test

The Kaufman Adolescent and Adult Intelligence Test (KAIT) (Kaufman & Kaufman, 1993) is an individually administered intelligence test for individuals between the ages of 11 and more than 85 years. It provides Fluid, Crystallized, and Composite IQs, each a standard score with a mean of 100 and a standard deviation of 15.

(i) Theory

The Horn–Cattell theory forms the foundation of the KAIT and defines the constructs believed to be measured by the separate IQs; however, other theories guided the test development process, specifically the construction of the subtests. Tasks were developed from the models of Piaget's formal operations (Inhelder & Piaget, 1958; Piaget, 1972) and Luria's (1973, 1980) planning ability in an attempt to include high-level, decision-making, more developmentally advanced tasks. Luria's notion of planning ability involves decision-making, evaluation of hypotheses, and flexibility, and "represents the highest levels of development of the mammalian brain" (Golden, 1981, p. 285).

Cattell and Horn (Cattell, 1963; Horn & Cattell, 1966, 1967) postulated a structural model that separates fluid from crystallized intelligence. Fluid intelligence traditionally involves relatively culture-fair novel tasks and taps problem solving skills and the ability to learn. Crystallized intelligence refers to acquired skill, knowledge, and judgments which have been taught systematically or learned via acculturation. The latter type of intelligence is influenced highly by formal and informal education and often reflects cultural assimilation. Tasks measuring fluid ability often involve more concentration and problem solving than crystallized tasks which tend to measure retrieval and application of general knowledge.

Piaget's formal operations depicts a hypothetical-deductive abstract reasoning system that has as its featured capabilities the generation and evaluation of hypotheses and the testing of propositions. The prefrontal areas of the brain associated with planning ability mature at about ages 11–12 years (Golden, 1981), the same ages that characterize the onset of formal operational thought (Piaget, 1972). The convergence of the Luria and Piaget theories regarding the ability to deal with abstractions is striking; this convergence provided the rationale for having age 11 as the lower bound of the KAIT, and for attempting to measure decision making and abstract thinking with virtually every task on the KAIT (Kaufman & Kaufman, 1993).

Within the KAIT framework (Kaufman & Kaufman, 1993), crystallized intelligence "measures the acquisition of facts an problem solving ability using stimuli that are dependent on formal schooling, cultural experiences, and verbal conceptual development" (p. 7). Fluid intelligence "measures a person's adaptability and flexibility when faced with new problems, using both verbal and nonverbal stimuli" (Kaufman & Kaufman, 1993, p. 7). It is important to note that this crystallized-fluid construct split is not the same as Wechsler's 1974, 1981, 1991) verbal–nonverbal split. This was documented in the results of a factor analysis done with the WISC-R and the KAIT that showed the KAIT crystallized subtests loaded highly on the Crystallized/Verbal factor (0.47–0.78), Fluid subtests loaded 0.51–0.88 on the Fluid factor, and Memory for Block Designs also loads 0.41 on the Perceptual Organization factor (Kaufman & Kaufman, 1993; Kaufman, Ishikuma, & Kaufman, 1994). The KAIT Fluid subtests stress reasoning rather than visual–spatial ability, include verbal comprehension or expression as key aspects of some tasks, and minimize the role played by visual-motor speed for correct responding. In addition, the KAIT scales measure what Horn (1989) refers to as broad fluid and broad crystallized abilities, rather than the purer and more specific skill areas that have emerged in Horn's expansion and elaboration of the original Horn–Cattell Gf-Gc theory.

The Core Battery of the KAIT is composed of three Crystallized and three Fluid subtests, and these six subtests are used to compute the IQs. The Expanded Battery also includes two supplementary subtests and two measures of delayed recall that evaluate the individual's ability to retain information that was learned previously in the evaluation during two of the Core subtests. The Core Battery of the KAIT consists of subtests one through six, and subtests one through 10 comprise the Expanded Battery. Each subtest except the supplementary Mental Status task yields age-based scaled scores with a mean of 10 and a standard deviation of three. Sample and teaching items are included for most subtests to ensure that examinees understand what is expected of them for each subtest.

The delayed recall subtests are administered, without prior warning, about 25 and 45 minutes after the administration of the original, related subtests. The two delayed recall subtests provide good measure of an ability that Horn (1985, 1989) calls TSR (Long-Term Storage and Retrieval). TSR "involves the storage of information and the fluency of retrieving it later through association" (Woodcock, 1990, p. 234).

The Mental Status subtest is comprised of 10 simple questions that assess attention and orientation to the world. Most normal adolescents and adults pass at least nine of the 10 items, but the task has special use with retarded and neurologically impaired populations. The Mental Status subtest may be used as a screener to determine if the KAIT can be validly administered to an individual.

(ii) Standardization and properties of the scale

The KAIT normative sample, composed of 2000 adolescents and adults between the ages of 11–94 years was stratified on the variables of gender, racial/ethnic group, geographic region, and SES (Kaufman & Kaufman, 1993).

Mean split-half reliability coefficients for the total normative sample were 0.95 for Crystallized IQ, 0.95 for Fluid IQ, and 0.97 for Composite IQ (Kaufman & Kaufman, 1993). Mean test–retest reliability coefficients, based on 153 identified normal individuals in three age groups (11–19, 20–54, 55–85 +), retested after a one-month interval, were 0.94 for Crystallized IQ, 0.87 for Fluid IQ, and 0.94 for Composite IQ (Kaufman & Kaufman, 1993). Mean split-half reliabilities of the four Crystallized subtests ranged from 0.89 to 0.92 (median = 0.90). Mean values for the four Fluid subtests ranged from 0.79 to 0.93 (median = 0.88) (Kaufman & Kaufman, 1993). Median test–retest reliabilities for the eight subtests, based on the 153 people indicated previously, ranged from 0.72 to 0.95 (median = 0.78). Rebus Delayed Recall had an average split-half reliability of 0.91 and Auditory Delayed Recall had an average value of 0.71; their respective stability coefficients were 0.80 and 0.63 (Kaufman & Kaufman, 1993).

Factor analysis, both exploratory and confirmatory, gave strong construct validity support for the Fluid and Crystallized Scales, and for the placement of each subtest on its designated scale. Crystallized IQs correlated 0.72 with Fluid IQs for the total standardization sample of 2000 (Kaufman & Kaufman, 1993).

Table 8 summarizes the results of correlational studies involving the KAIT and other well known intelligence tests. The values shown in Table 8 support the construct and criterion-related validity of the three KAIT IQs.

Two separate exploratory joint factor analyses were conducted to analyze the KAIT with both the WISC-R and the WAIS-R. Data were obtained from 118 adolescents in the WISC-R sample and 338 adults in the WAIS-R sample. Two-, three-, four-, five-, and six-factor solutions were examined for each analysis using both varimax and oblimin rotations. Three robust factors came out in the three-factor solutions for both the WISC-R and the WAIS-R. Loadings from the first unrotated principal factor (*g* loadings) along with the three-factor solution for the joint analysis of the KAIT and the WISC-R are presented in Table 9. The analogous data for the KAIT and WAIS-R are presented in Table 10.

The results of these joint analyses indicate that the Wechsler subtests and KAIT subtests are about equal as measures of general intelligence. The KAIT subtests have a mean *g* loading of 0.71 and the Wechsler subtests also have a mean *g* loading of 0.71. The most important finding from these analyses is that the

Table 8 Correlations of the three KAIT IQs with standard scores and IQs yielded by other major intelligence tests

Scale		*Age*	*Sample size*	*KAIT crystallized*	*KAIT fluid*	*KAIT composite*

Source: Kaufman and Kaufman (1993).

KAIT Fluid subtests and Wechsler Performance subtests seem to measure markedly different constructs. The Fluid and Perceptual Organization factors correlate about as highly with each other as they do the Crystallized/Verbal Factor. The differences between Fluid IQ and Perceptual Organization abilities have been studied and discussed by Woodcock (1990). Woodcock presented evidence that Wechsler's Performance IQ primarily measures Horn's Gv or broad visualization, and not fluid intelligence.

The KAIT benefits from an integration of theories that unite developmental (Piaget), neuropsychological (Luria), and experimental-cognitive (Horn–Cattell) models of intellectual functioning. The theories work well together and do not compete with one another. Together, the theories give the KAIT a solid theoretical foundation that facilitates test interpretation across the broad 11–94-year age range on which the battery was normed.

The changes in crystallized and fluid abilities on the KAIT were examined in a study of 1500 adults aged 17–94 (Kaufman & Horn, 1996). The results of this study indicated that fluid reasoning (Gf) declined steadily across adulthood, and this decline accelerated during the period beginning at about age 55. This finding that fluid ability reaches a peak in development in young adulthood and declines thereafter, at first quite gradually, but more rapidly as age progresses, is in agreement with results from previous research, although a more steep decline in ability was found in the research directed by Horn (1985). Through the 20s, the measure of crystallized knowledge was found to increase, but then showed no increase or decrease until about age 60. Similar findings have been reported in other cross-sectional investigations of fluid and crystallized measures (Kaufman, Kaufman, Chen, & Kaufman, 1996). After age 60, crystallized knowledge was found to decrease as well. Individual differences in education, gender, and ethnicity were found not to alter the basic findings (Kaufman & Horn, 1996).

The KAIT has also been examined with respect to its relationship to adult interests, as demonstrated on the Strong Interest Inventory (SII; Hansen & Campbell, 1985). Kaufman and McLean (1992, November) examined 936 individuals who were administered both the KAIT and the SII. The SII includes six General Occupational Themes (GOTs), including Realistic, Investigative, Artistic, Social,

Enterprising, and Conventional. The findings indicated that there were two General Occupational Themes that produced substantial mean differences between IQ levels. Individuals with higher IQ were more Investigative and more Artistic (Artistic mean score = 49) than those with average IQ (Artistic mean score = 45) or low IQs (Artistic mean score = 42). The authors explain that in light of the Investigative person's interest in science and in solving abstract problems, the relationship of the Investigative theme to IQ level makes sense. The relationship between the Artistic theme and IQ was not hypothesized by the researchers, but was nonetheless significant, even with the effect of Investigative partialed out.

An examination of the KAIT with the Myers–Briggs Type Indicator has been conducted to understand more clearly the commonly accepted relationship between personality style and cognition (Kaufman, McLean, & Lincoln, 1996). The researchers had hypothesized that subjects who favored Intuition and Thinking on the Myers–Briggs would be more intelligent and would also favor fluid over-crystallized intelligence, compared to those subjects who favored Sensing and Feeling on the Myers–Briggs. Just as hypothesized, individuals classified as Intuitive earned higher KAIT Composite IQs than those classified as Sensing. However, the Fluid IQ was not found to be favored over the Crystallized IQ, as had been predicted (Kaufman et al., 1996). Thus, a modest association is present between personality dimensions and intellectual ability (as evidenced on the Myers–Briggs and KAIT).

4.08.2.1.8 Overview

The KAIT represents a reconceptualization of the measurement of intelligence that is more consistent with current theories of intellectual development (Brown, 1994). The fluid-crystallized dichotomy, the theory underlying the KAIT, is based on the original Horn–Cattell theory of intelligence, thus offering a firm and well researched theoretical framework (Flanagan, Alfonso, & Flanagan, 1994). The fluid-crystallized dichotomy enhances the richness of the clinical interpretations that can be drawn from this instrument (Brown, 1994). The test materials are well constructed and attractive,

and the manual is well organized and helpful (Dumont & Hagberg, 1994; Flanagan et al., 1994). Furthermore, the test materials are easy to use and stimulating to examinees (Flanagan et al.).

"The KAIT has been standardized by state-of-the-art measurement techniques" (Brown, 1994). The psychometric properties of the KAIT regarding standardization and reliability are excellent and the construct validity evidence that is reported in the manual provides a good foundation for its theoretical underpinnings (Flanagan et al., 1994).

The theoretical assumption that formal operations is reached by early adolescence limits that application of the KAIT with certain adolescent and adult populations (Brown, 1994). If an individual has not achieved formal operations, many of the subtests will be too difficult for them and perhaps frustrating and overwhelming. Examiners should be aware of this limitation when working with such individuals in order to maintain rapport. The KAIT can be a useful assessment tool when working with high-functioning, intelligent individuals; however, it can be difficult to use with borderline individuals and some elderly clients. Elderly clients' scores on some of the subtests may be negatively impacted by poor reading, poor hearing, and poor memory (Dumont & Hagberg, 1994).

Flanagan et al. (1994) report that the inclusion of only three subtests per scale may limit or interfere with the calculation of IQs if a subtest is spoiled. The usefulness of the Expanded Battery and Mental Status subtest of clinical populations is questionable given the reliability and validity data presented in the manual, suggesting that interpretations be made with caution (Flanagan et al.).

Although there clearly are some limitations in the use of the KAIT with some populations, overall, the test appears to be well thought out and validated (Dumont & Hagberg, 1994). The KAIT represents an advancement in the field of intellectual assessment with its ability to measure fluid and crystallized intelligence from a theoretical perspective and, at the same time, maintain a solid psychometric quality (Flanagan et al., 1994).

4.08.2.1.9 The Stanford–Binet: Fourth edition

(i) Theory

Like its predecessors, the fourth edition is based on the principal of a general ability factor, *g*, rather than on a connection of separate functions. The fourth edition has maintained, albeit to a much lesser degree, its adaptive testing format. No examinee takes all the items on the scale, nor do all examinees of the same chronological age respond to the same tasks. Like its predecessors, the scale provides a continuous appraisal of cognitive development from ages two through young adult.

One of the criticisms in the previous versions is that they tended to underestimate the intelligence of examinees whose strongest abilities did not lie in verbal skills (or overestimate the intelligences of those whose verbal skills excelled). Therefore, consideration when developing the Binet IV was to give equal credence to several areas of cognitive functioning. The authors set out to appraise verbal reasoning, quantitative reasoning, abstract/visual reasoning, and short-term memory (in addition to a composite score representing *g*).

This model is based on a three-level hierarchical model of the structure of cognitive abilities. A general reasoning factor is at the top level (*g*). The next level consists of three broad factors: crystallized abilities, fluid analytic abilities, and short-term memory. The Horn–Cattell theory forms a foundation for the test, with measures of Gc being Verbal and Quantitative, and Abstract-Visual being a Gf scale. The third level consists of more specific factors, similar to some of Thurstone's eight primary mental factors: verbal reasoning, quantitative reasoning, and also abstract/visual reasoning. The selection of these four areas of cognitive abilities came from the authors' research and clinical experience of the kinds of cognitive abilities that correlate with school progress.

The Binet IV contains previous tasks, combining old with new items, and some completely new tasks. In general, test items were accepted if (i) they proved to be acceptable measurements of the construct, (ii) they could be reliably administered and scored, (iii) they were relatively free of ethnic and/or gender bias, and (iv) they functioned adequately over a wide range of age groups.

(ii) Standardization and properties of the scale

Standardization procedures followed 1980 US Census Data. There appears to be an accurate sample representation from geographic region, size of community, race/ethnic group, and gender. The standardization falls short, however, in terms of age, parental occupation, and parental education. The total sample size was large (5013), with age representation extending from two years to 23 years, 11 months. The concentration of the sample is on children aged 4–9 years old (41%). Not only were adults 24 years and older not represented, but also representation beyond age 17 years, 11 months was negligible (4%).

In order to assess characteistics of SES, information regarding parental occupation and parental education was obtained. A review of Table 11 demonstrates that children whose parents came from managerial/professional occupations and or who were college graduates and beyond were grossly over-represented in the sample. In other words, the norms are based on a large percentage of individuals from upper-socioeconomic classes. In order to adjust for this discrepancy, a weighting procedure was applied, which makes the norming sample suspect. Unquestionably, SES has been shown time and again to be the single most important stratification variable regarding its relationship to IQ (Kaufman, 1990, Chapter 6; Kaufman & Doppelt, 1976).

Internal consistency estimates for the Stanford–Binet IV Composite Scale are excellent, ranging from 0.95 to 0.99 across the age groups (median = 0.97) (Sattler, 1988). The internal reliabilities are also high for the Verbal Reasoning, Abstract/Visual Reasoning, Quantitative Reasoning, and Short-term Memory Area scores (typically in the upper 0.80s–0.90s). Subtest reliabilities are also good, with the exeption of Memory for Objects which had a median of 0.73 (Thorndike et al., 1986b). Test–retest reliability estimates are also good for preschool (Composite coefficient = 0.91) and elementary school aged (Composite coefficeint = 0.90) samples (Thorndike, Hagen, & Sattler, 1986a). From an internal reliability perspective, this measure is generally good.

Construct validity for *g* and for the four factors was studied using a variant of confirmatory factor analysis. The subtests had impressive high to substantial loadings on *g* (0.51–0.79). Unfortunately, the four factors were given weak support by the confirmatory procedure. Additionally, exploratory factor analysis gave even less justification for the four Binet Scales; only one or two factors were identified by Reynolds, Kamphaus, and Rosenthal (1988) for 16 of the 17 age groups studied. Clearly, the factor analytic structure does not conform to the theoretical framework used to construct the test. Therefore, once again the composite score is left as the only clearly valid representation of a child's cognitive abilities.

Table 11 Representation of the Stanford–Binet fourth edition.

	Sample percent	*US population percent*
By parental occupation		
Managerial/professional	45.9	21.8
Technical sales	26.2	29.7
Service occupations	9.7	13.1
Farming/forestry	3.2	2.9
Precision production	6.7	13.0
Operators, fabricators, other	8.3	9.5
Total	100.0	100.0
By parental education		
College graduate or beyond	43.7	19.0
1–3 years of college	18.2	15.3
High school graduate	27.5	36.5
Less than high school	10.6	29.2
Total	100.0	100.0

Correlational studies, using nonexceptional children, between the Binet IV and the Stanford–Binet (Form L-M), WISC-R, WAIS-R, WPPSI, K-ABC have ranged from 0.80 to 0.91 (comparing full-scale composites). Correlational studies using exceptional children (gifted, learning impaired, mentally retarded) produced generally lower correlations, probably because of restricted variability in the test scores. For example, for gifted students the mean composite score on the Binet IV correlated 0.69 with the WISC-R Full Scale IQ. These data and data from similar validity investigations are presented more extensively in the *Technical manual* for the Binet IV (Thorndike et al., 1986a). Despite the presentation of ample evidence of concurrent validity, the substantial problems with construct validity, the data collection method, and other difficulties with the Binet IV have led at least one reviewer to recommend that the battery be laid to rest (Reynolds, 1987): "To the S-B IV, *Requiescat in pace*" (p.141).

(iii) Overview

The Binet IV was developed in an attempt to increase the popularity of the test as well as address some of the negative reviews that had plagued the previous edition. The test authors attempted to make the fourth edition significantly different from the previous L-M edition; however, it appears that this goal has achieved only limited success. Canter (1990) describes the "rebirth" of the Binet as giving way to "confusion and even dismay as the primary consumers of intelligence tests learned that the new edition offered a more complicated route to the same destination." Another reviewer describes the Binet IV as "in most respects, a completely new version of a very old test" (Spruill, 1987). This author also questioned whether or not the weighting procedure that was used to correct for sample bias was adequate (Spruill, 1987) that was not outweighed by the large size of the standardization sample. Finally, it is not clear why a test described as for individuals aged two to adult does not include persons over the age of 23 in the standardization sample.

Although there appears to be a number of difficulties with the Binet IV, the test is still used and it is not without its strengths. The administration of some of the subtests allow the examiner flexibility, and young children seem to find the items challenging and fun. The scale has excellent internal reliability and provides a flexible administration format. Despite its shortcomings, Binet IV continues to be a very good assessment of cognitive skills related to academic progress (Spruill, 1987). It also includes several excellent, well-constructed tasks that offer valuable information when they are administered in addition to the Wechsler scales (Kaufman, 1990, 1994b).

4.08.2.1.10 Woodcock–Johnson Psycho-Educational Battery-Revised: tests of cognitive ability (WJ-R)

The WJ-R is one of the most comprehensive test batteries available for the clinical assessment of children and adolescents (Kamphaus, 1993). The WJ-R is a battery of tests for individuals from age 2 to 90 + , and is composed of two sections, Cognitive and Achievement. The focus of this discussion is the Cognitive portion of the WJ-R battery.

(i) Theory

The WJ-R Cognitive battery is based on Horn's (1985, 1989) expansion of the Fluid/Crystallized model of intelligence (Kamphaus, 1993; Kaufman, 1990). The standard and supplemental subtests of the WJ-R are aligned with eight of the cognitive abilities isolated by Horn (1985, 1989) (Kamphaus, 1993; Kaufman 1990). The cognitive battery measures seven Horn abilities: Long-term Retrieval, Short-term Memory, Processing Speed, Auditory Processing, Visual Processing, Comprehension-knowledge, and Fluid Reasoning. An eighth ability, Quantitative Ability, is measured by several Achievement subtests on the WJ-R.

The four subtests that measure Long-term Retrieval (Memory for Names, Visual–Auditory Learning, Delayed Recall/Memory for Names, Delayed Recall/Visual–Auditory Learning), require the subject to retrieve information stored minutes or a couple of days earlier. In contrast, the subtests that measure Short-term Memory (Memory for Sentences, Memory for Words, Numbers Reversed) require the subject to store information and retrieve it immediately or within a few seconds. The two Processing Speed subtests (Visual Matching, Cross Out) assess the subject's ability to work quickly, particularly under pressure to maintain focused attention.

Within the Auditory Processing domain, three subtests (Incomplete Words, Sound Blending, Sound Patterns) assess the subject's ability to perceive fluently patterns among auditory stimuli. The three Visual Processing subtests (Visual Closure, Picture Recognition, Spatial Relations) assess the subject's ability to manipulate fluently stimuli that are within the visual domain.

Picture Vocabulary, Oral Vocabulary, Listening Comprehension, and Verbal Analogies are the four subtests that are linked to the Comprehension-knowledge factor, also known as crystallized intelligence within Horn's theoretical model. These subtests require the subject to demonstrate the breadth and depth of their knowledge of a culture. Analysis-synthesis, Concept Formation, Spatial Relations, and Verbal Analogies (which also loads on the Comprehension-knowledge factor) assess the subject's Fluid Reasoning, or "new" problem-solving ability. Finally, from the Achievement portion of the WJ-R, both the Calculation and Applied Problems subtests assess the individual's Quantitative Ability.

The cognitive battery consists of 21 subtests, seven of which comprise the standard battery; the remaining 14 are part of the supplemental battery (one per ability as described by Horn). There are two composite scores, Broad Cognitive Ability and Early Development (for preschoolers), which are both comparable to an overall IQ. The individual subtest scores as well as the composite scores have a mean of 100 and a standard deviation of 15.

Computer software is available for scoring the WJ-R and is essential if all of the information is to be obtained that the WJ-R is capable of providing. The WJ-R provides the examiner with percentile ranks, grade-based scores, age-based scores, and the Relative Mastery Index (RMI). The RMI is a unique kind of ratio, with the second part of the ratio set at a value of 90. The denominator of the ratio means that children in the norm sample can perform the intellectual task with 90% accuracy. The numerator of the ratio refers to that child or adolescent's proficiency on that subtest (Kamphaus, 1993). For example, if a child obtains an RMI of 60/90, it would mean that the child's proficiency on the subtest is at a 60% level whereas the typical child of that age (or grade) mastered the material at a 90% level of accuracy.

The entire battery is quite lengthy and therefore can be timely to administer. The seven-subtest Standard Battery takes approximately 40 minutes to administer; however, all the clinician will obtain from it is, essentially, a measure of *g*. In order to obtain all of the information that the WJ-R is capable of providing, a clinician should administer most of the subtests in both the Cognitive and Achievement batteries. Administration of a thorough cognitive and achievement assessment using the WJ-R would take approximately 3.5–5 hours depending on the subject's age, abilities, and speed. However, individual subtests may be administered to test specific hypothesis without administering the entire battery. The WJ-R tests also provides measures of differential scholastic aptitudes including reading, mathematics, written language, and knowledge. An aptitude-achievement comparison may be made if the WJ-R Tests of Achievement are given in addition. Such a discrepancy reflects the amount of disparity between certain intellectual capabilities of an individual and their actual academic performance.

Evidence has been presented that supports the use of the WJ-R, standard cognitive and achievement tests in the identification and classification of school-aged children as gifted, learning-disabled, and mentally retarded (Evans, Carlsen, & McGrew, 1993). Significant group differences were found on mean scores of all WJ-R standard cognitive and achievement clusters. Together, the WJ-R cognitive and achievement demonstrated the ability to predict group membership (gifted, L.D., or M.R.). This was shown in an overall classification agreement of 93.5% for ages 8–10 and 84.3% for ages 16–18. These levels of classification agreement support the use of the WJ-R batteries in the identification of exceptional students (Evans et al., 1993). It should be noted, however, that clinicians must supplement the process of assessment and diagnosis by including other factors beyond statistical classification, such as social-emotional considerations, medical conditions, vision and hearing measures, and other environmental considerations, to make the determination of classification of the aforementioned groups.

(ii) Standardization and properties of the scale

The WJ-R was normed on a reasonably representative sample of 6359 individuals selected to provide a cross-section of the US population aged 2–90+ (Woodcock & Mather, 1989). The sample included 705 preschool children, 3245 students in grades K-12, 916 college/university students, and 1493 individuals aged 14–90+ who were not enrolled in school. Stratification variables included gender, geographic region, community size, and race. However, Kaufman (1990) reports that, although representation on important background variables was adequate, it was necessary to use a weighting procedure to adjust the data that was collected so it would match US population statistics.

The internal consistency estimates for the standard and supplemental battery subtests are good, with median scores from ages 2 to 79 ranging from 0.69 to 0.93. The Broad Cognitive Ability composite score for the seven standard battery subtest yields a median internal consistency coefficient of 0.94 and the Broad Cognitive Ability Early Development Scale yields a coefficient of 0.96 at ages two and four (Kamphaus, 1993).

The validity of the WJ-R has been called into question when used with a learning disabilities population (Hoy et al., 1993). This is because the mean broad cognitive ability scores from the WJ-R Tests of Cognitive Ability have been found to be one standard deviation lower than mean full scale scores on the WISC-R. However, in an adult sample, significant and consistently high correlations were found between the WAIS-R and the WJ scores (Siehen, 1985). Hoy et al. studied 27 male and 20 university students with a previously diagnosed learning disability, as well as 47 learning disabled individuals from a rehabilitation clinic. The results indicated a low positive correlation between the WJ-R broad cognitive score and the WAIS-R Verbal Scale scores ($r = 0.44$) for the rehabilitation subjects, but a more moderate positive correlation was found for the university subjects ($r = 0.73$). The WAIS-R Full Scale IQ also correlated moderately with the Broad Cognitive in university subjects ($r = 0.72$), and had a lower correlation with rehabilitation subjects ($r = 0.58$). The correlation between WJ-R Broad Cognitive Scores and the Performance Scale IQ was low for both the university and rehabilitation subjects ($r = 0.40$). The low correlation between the PIQ and Broad Cognitive suggests that the two instruments are providing different information, and are therefore both potentially useful.

(iii) Overview

The WJ-R Cognitive battery was developed based on Horn's expansion of the Cattell–Horn Fluid–Crystallized model of intelligence. This theoretical rationale allows for further empirical analysis of both the WJ-R and the theory (Webster, 1994). The standardization of the battery appears to be sound and the various age groups are represented adequately.

The Cognitive battery is quite thorough and, when administered in its entirety, can provide the examiner with a wealth of information about an individual's intellectual functioning and abilities. The test materials and manuals are easy to use and well designed. The administration is fairly simple; however, scoring the test, especially when the Achievement battery is administered as well, can be quite a lengthy and, initially, a difficult process. The scoring can be done by hand but is done more efficiently with the computer scoring program. The computer scoring program is easy to use and provides the examiner with the individual's raw scores, standard scores, percentile ranks, and age and grade equivalents for each subtest (Webster, 1994).

The WJ-R Cognitive battery is a well standardized test developed on a theory of intelligence. However, the test is not without shortcomings. Webster (1994) raises issues with the specific psychometric procedures used in developing test items. Data are lacking that show the efficacy of the WJ-R to predict, from a time based perspective, actual functional levels of academic achievement and to identify children at risk for failure early in the educational process (Webster, 1994). Kaufman (1990) points to another shortcoming with the small number of tests that comprise each scale. The Standard Scale measures each of the seven scales with one subtest apiece.

The *Woodcock–Johnson Psycho-Educational Battery: Revised examiner's manual* reports that

"Items included in the various tests were selected using item validity studies as well as expert opinion" (Woodcock & Mather, 1989, p. 7). Kamphaus (1993) states that the manual should have included more information on the results of the experts' judgments or some information on the methods and results of the studies that were used to assess validity.

It is clear that the WJ-R Cognitive battery is quite comprehensive, providing the clinician with a wealth of information. The standardization sample is large, the factor loadings reveal generally strong factor analytic support for the construct validity for the battery for adolescents and adults, and the reliability coefficients are excellent (Kaufman, 1990).

4.08.2.1.11 Detroit Tests of Learning Aptitude (DTLA-3)

DTLA-3 was developed by Hammill (1991) and was designed to measure different, but interrelated, mental abilities for individuals aged six through 17 years, 11 months. It is a battery of 11 subtests and yields 16 composites that measure both general intelligence and discrete ability areas. Hammill and Bryant (1991) report that the DTLA-3 was influenced greatly by Spearman's two-factor theory (1927). This theory of "aptitude" consisted of a general factor *g* that is present in all intellectual pursuits, and specific factors that vary from task to task (McGhee, 1993).

The 11 subtests are used to form the 16 composite scores. The subtests are grouped into different combinations according to various hypothetical constructs that exist in theories of intelligence and information processing. In general, the composite scores estimate general mental ability; however, they all do so in a somewhat different manner. The General Mental Ability Composite is formed by combining the standard scores of all 11 subtests, and, thus, has been referred to as the best estimate of *g*. The Optimal Level Composite is composed of the four largest standard scores that the individual earns. This individualized score is often referred to as the best estimate of a person's overall "potential." The Domain Composites may be divided into three areas: Linguistic, Attentional, and Motoric. Furthermore, there is a Verbal and Nonverbal Composite in the Linguistic domain, an Attention-enhanced and Attention-reduced Composite in the Attentional Domain, and a Motor Enhanced and a Motor-reduced composite in the Motoric Domain. Finally, there are the Theoretical Composites of the DTLA-3 on which the battery's subtests are constructed. The major theories that the subtests were developed from include Horn and Cattell's (1966) fluid and crystallized intelligences, Das' (1973) simultaneous and successive processes, Jensen's (1980) associative and cognitive levels, and Wechsler's (1974, 1981, 1989) verbal and performance scales.

The DTLA-3 yields five types of scores: raw scores, subtest standard scores, composite quotients, percentiles, and age equivalents. Standard scores for the individual subtests have a mean of 10 and a standard deviation of three and the Composite Quotients have a mean of 100 and a standard deviation of 15.

The individual subtest reliabilities range from 0.77 to 0.94, with a median of 0.87, and the averaged alphas for the composites ranged from 0.89 to 0.96, with a median of 0.94. To assess the DTLA-3's stability over time, the test–retest method was used with a sample of 34 children residing in Austin, Texas. The children, aged six through 16, were tested twice, with a two-week period between testings (Hammill, 1991). The results of this test–retest analysis indicate that individual subtest reliabilities range from 0.75 to 0.96, with a median of 0.84, and Composite reliabilities range from 0.81 to 0.96, with a median of 0.90.

(i) Overview

The DTLA-3 was designed to measure both general intelligence and discrete abilities for children aged six through 17 years, 11 months. The DTLA-3 is not grounded in one specific theory but rather can be linked to a number of different theorists and their views on intelligence and achievement. This "eclectic" theorizing has resulted in the DTLA-3's numerous subtests, composites and various combinations of the two that yield potentially important information about an individual's abilities.

Reliability and validity studies are encouraging but are based on specific and limited samples (VanLeirsburg, 1994). Additional research in this area would be beneficial. Furthermore, test–retest reliability data were collapsed across age levels, which makes it impossible to determine the stability of scores of the various age levels (Schmidt, 1994). The standardization sample was representative of the US population but more information on socioeconomic level is needed (Schmidt, 1994). Also, there is no normative data reported for subjects with handicapping conditions and sample stratification for age was not equalized (VanLeirsburg, 1994).

The testing manual suggests that individual testing time may vary but that on average it takes 50 minutes to two hours to administer. Scoring and interpretation of the results is easy, yet it can be quite time consuming without the aid of the computer program (VanLeirsburg, 1994). Despite apparent shortcomings, the DTLA-3 may be useful for eligibility or placement purposes as well as a useful research tool (Schmidt, 1994).

4.08.2.1.12 Differential Abilities Scales (DAS)

The DAS was developed by Elliott (1990) and is an individually administered battery of 17 cognitive and achievement tests for use with individuals aged 2.5 through 17 years. The DAS Cognitive Battery has a preschool level and a school-age level. The school-age level includes reading, mathematics, and spelling achievement tests that are referred to as "screeners." The same sample of subjects was used to develop the norms for the Cognitive and Achievement Batteries; therefore, intra- and intercomparisons of the two domains are possible.

The DAS is not based on a specific theory of intelligence. Instead, the test's structure is based on tradition and statistical analysis. Nonetheless, the test is not theory free, and, in fact, is based in part on *g* and the view of intelligence as hierarchical in nature (McGhee, 1993). Elliott (1990) described his approach to the development of the DAS as "eclectic" and cited researchers such as Cattell, Horn, Das, Jensen, Thurstone, Vernon, and Spearman. Indeed, there are some clear-cut relationships between several DAS scales and theoretical constructs. For example, Horn's (1985, 1989) concepts of fluid and crystallized intelligence are measured quite well by the Nonverbal Reasoning and Verbal Ability scales, respectively. Elliott endorses Thurstone's ideas that the emphasis on intellectual assessment should be on the assessment and interpretation of distinct abilities (Kamphaus, 1993). He also stresses that in the assessment of children with learning and developmental disabilities, clinicians need more fine detail than is provided by a global IQ score (Elliott, 1997). Therefore, subtests were constructed to emphasize their unique variance which should translate into unique abilities. Although it was expected that meaningful composites would be derived from the subtests, the primary focus in test development was at the subtest level. One of the main distinctions between the DAS and other batteries is its emphasis on the subtest level.

Elliott (1997) noted how in psychology there has long been a link between cognitive abilities and neurological structure. The DAS uses the link between the factor structure of abilities and the neurological evidence of the nature of the structures. For example, the DAS has two major ability clusters which reflect two major systems for receiving, perceiving, remembering, and processing information in the visual and auditory modalities. The systems are represented by Verbal and Visualization/Spatial factors. There is strong neuropsychological evidence for the existence of these systems (Elliott, 1997), which tend to be specific in the left and right cerebral hemispheres, respectively. The DAS specifically measures each of these factors by the Verbal cluster and the Spatial Cluster.

Normally, the auditory and visual systems do not operate completely independently. There is interaction of the systems. The integrative system is represented factorally by the fluid reasoning factor in the Cattell–Horn theory. Analysis of both verbal and visual information is usually required in measures of fluid reasoning. The neuropsychological function is an integrative system of the frontal lobe, which is critical to complex mental functioning (Luria, 1973). The DAS measures fluid ability by the Nonverbal Reasoning cluster, which requires integrated analysis and transformation of both visual and verbal information.

Elliott (1997) notes that there is much evidence from cognitive psychology that indicates that verbal and visual short-term memory systems are quite distinct. However, some cognitive tests (i.e., Stanford–Binet IV) represent memory with a single factor. The DAS, on the other hand, represents visual and auditory short-term memory with distinct measures, rather than with one unitary task. The DAS also provides a measure of intermediate-term memory (in the Horn–Catell model), which is usually measured by tasks that have both verbal and visual components. The DAS has a measure in which pictures are presented, but they have to be recalled verbally (Recall of Objects). This visual–verbal short-term memory measures another distinct information processing system (Elliott, 1997).

The cognitive portion of the DAS consists of "core" and "diagnostic" subtests designed to assess intelligence at the preschool level and the school-age level. The core subtests measure complex processing and conceptual ability, which is strongly *g*-related. The diagnostic subtests measure less cognitively complex functions, such as short-term memory and processing speed, thereby having less of a *g*-saturation (Elliott, 1997). The achievement portion measures skills in the areas of word reading, spelling, and basic number skills. The core subtests are averaged to obtain the General Conceptual Ability (GCA) score and, depending on the age of the individual, additional composite scores are calculated which are referred to as Cluster scores.

The individual Cognitive subtests have a mean of 50 and a standard deviation of 10. The GCA scores, Cluster scores, and Achievement scores, have a mean of 100 and a standard deviation of 15. Percentile ranks, age equivalents, and score comparisons are also available in the examiner's manual. Score comparisons provide a profile analysis and allow the examiner to ascertain information regarding aptitude-achievement discrepancies.

Interpretation of the DAS subtests and composites is facilitated by the framework provided in the *Handbook* (Elliott, 1990). Elliott (1990) notes one positive aspect of interpreting the DAS is that the "design of scoring procedures on the Record Form enables statistically significant high and low scores to be identified immediately" (p. 37). Significant discrepancies between subtests, cluster scores, and ability and achievement can be obtained immediately. Like Kaufman's (1994b) approach to interpreting the WISC-III, an ipsative approach is used to examine differences between subtests, requiring the examiner to compare the child's mean score on core subtests to his or her individual subtest scores. Discrepancy between ability and achievement is analyzed by examining the GCA (or Special Nonverbal Composite) and each of the achievement tests.

(i) Standardization and properties of the scale

Elliott (1997) noted that exceptionally careful and effective standardization and data-analytic procedures were used in the development of the DAS. The DAS was standardized on 3475 children tested between 1987 and 1989. The normative sample includes 200 cases for each age level between the ages of five and 17. The younger part of the sample consisted of 350 children between the ages of 2.5 year, and four years, 11 months. Exceptional children were also included in the standardization sample. Gender, race, geographic region, community size, and enrollment (for ages 2–5 through 5–11) in an educational program were controlled. SES was estimated using the average education level of the parent or parents living with the child (Kamphaus, 1993).

Over and above the requirements of the norm sample, an additional 600 cases of Black and Hispanic children were collected. The reason that this oversample was collected was to perform statistical analysis for item bias and prediction bias. The test developers wanted to ensure that the rules for scoring would be sensitive to minority children's responses (Elliott, 1997). Only a small number of items were deleted due to item bias, and there was "no evidence" that the DAS is biased against either Blacks or Hispanics, compared with Whites (Elliott, 1990).

The DAS has a median reliability estimate of 0.95 for the GCA. Internal consistency reliability estimates for the cluster scores range from 0.83 for Nonverbal Reasoning at age five to 0.94 for Spatial at several ages (Kamphaus, 1993). The test–retest reliability coefficients for the preschool composite scores are 0.84 for Verbal Ability and 0.79 for Nonverbal Ability. The individual subtests' reliabilities vary with an average coefficient of 0.78.

Correlational research has shown good evidence of concurrent validity for the DAS (Kamphaus, 1993). With a sample of 27 children aged 7–14, the WISC-III Full Scale IQ correlated very highly with the DAS GCA score (0.92), and the WISC-III Verbal IQ score correlated highly with the DAS Verbal Ability score (0.87). The WISC-III Performance IQ correlated 0.78 with Nonverbal Reasoning and 0.82 with Spatial Ability. Additionally, the DAS Speed of Information Processing subtest score correlated 0.67 with the WISC-III Processing Speed Index score. The Binet IV Composite IQ correlated 0.88 with the DAS GCA for nine- and 10-year-olds and 0.85 with the DAS GCA for a sample of gifted children. The K-ABC Mental Processing Composite correlated 0.75 with the DAS GCA for 5–7-year-olds (Kamphaus, 1993).

Elliott (1997) presents three validity studies not published in the DAS manual. One of these studies included a confirmatory factor analysis of the DAS by Keith (1990), which concluded that "the constructs measured by the DAS are remarkably consistent across overlapping age levels of the test" (Elliott, 1997, p. 20). Elliott also discusses a joint factor analysis of the DAS and WISC-R. In a reanalysis of data, Elliott (in press) reported five factors emerging: crystallized intelligence (including DAS verbal and WISC-R verbal subtests), spatial or broad visualization (including DAS spatial and four of the five major WISC-R Performance subtests), nonverbal reasoning or fluid intelligence (defined only by DAS Nonverbal Reasoning subtests), auditory short-term memory, and speed of processing.

(ii) Overview

In general, the professional reviews of the DAS seem to be quite positive. Sandoval (1992) reports that the DAS is one of the least biased tests available. The test appears to be a relatively culture fair measure; however, its use with linguistically different children needs to be explored further (Sandoval, 1992). In examining different cultural group's performance on the

DAS, the group differences found typically to be present on traditional IQ tests are also found on the DAS. For example, African-American and Hispanic children score between half and two-thirds of a standard deviation below White children, and Asian children score above White children on all but verbal areas of the test. Caution is necessary when assessing Hispanic children because the DAS overpredicts achievement for this group based upon group achievement results (Bain, 1991). The author of the DAS suggests that children who are not proficient in English be given the nonverbal tests on the Special Nonverbal scale in the primary language. However, this can be problematic as the test developers did not provide directions in other common languages, such as Spanish. In addition, the utility of the English norms for assessing a child who is administered the test in Spanish or another non-English language has not been explored.

The DAS manual has recommendations for administering the test to deaf or limited-English-proficient children, however, these recommendations are lacking in a couple of areas. Braden (1992) notes, "The recommendations that age equivalents be used to represent the performance of retarded person is common, but it is potentially misleading" (p. 93). Another problem with the recommendations is that no mention is made of the use of interpreters for hearing-impaired children and nonverbal children, which may have a detrimental effect on deaf children's test scores.

According to Braden (1992), the Technical Manual includes extensive research data which suggest that the DAS is a psychometric improvement over existing techniques for measuring intellectual abilities and for determining intracognitive and aptitude-achievement discrepancies. The GCA of the DAS is largely independent of tasks known to be difficult for learning disabled children and is able to assist in the identification of learning disabilities or processing deficits.

The DAS can be a useful tool in assessing intelligence and achievement in both children and adolescents. However, there are a few characteristics of the DAS which do not promote ease of administration, especially for novices (Braden, 1992). These difficulties include having to apply two rules for subtest discontinuation, and having to convert raw scores to ability scores prior to obtaining subtest scaled scores. The DAS examiner's manual provides interpretive information and a framework for interpretation for the composite scores and subtests. The level and/or depth of information that the interpretative portion of the manual provides is quite thorough and is easy to use, making interpretation of the profiles, and individual and composite scores much easier.

4.08.2.1.13 Cognitive Assessment System (CAS)

(i) Theory

The Das–Naglieri Cognitive Assessment System (Naglieri & Das, 1996) was developed according to the Planning, Attention, Simultaneous, and Successive (PASS) theory of intelligence. The subtests are organized into four scales designed to provide an effective measure of the PASS cognitive processes. Planning subtests require the child to devise, select, and use efficient plans of action to solve the test problems, regulate the effectiveness of the plans, and self-correct when necessary. Attention tests require the child to selectively attend to a particular stimulus and inhibit attending to distracting stimuli. Simultaneous processing tests require the child to integrate stimuli into groups to form an interrelated whole and Successive processing tests require the child to integrate stimuli in their specific serial order or appreciate the linearity of stimuli with little opportunity for interrelating the parts.

The CAS yields Planning, Attention, Simultaneous, Successive, and Full Scale normalized standard scores (mean of 100 and standard deviation of 15). The Planning scale's subtests include Matching Numbers, Planned Codes, Planned Connections, and Planned Search; the Attention scale subtests include Number Detection, Receptive Attention, and Expressive Attention; the Simultaneous Scale subtests are Nonverbal Matrices, Verbal–Spatial Relations, and Figure Memory; and the Successive Scale subtests are Word Series, Sentence Repetition, Sentence Questions, and Successive Speech Rate. All subtests are set at a normative mean of 10 and SD of three.

(ii) Standardization and properties of the scale

The CAS was standardized on 2200 children ranging in age from five through 17 years. The sample was stratified by age, gender, race, ethnicity, geographic region, and parent education according to US. Census reports and closely matches the US population characteristics on the variables used. In addition to administration of the CAS, most of the standardization sample was also administered several achievement tests from the Woodcock–Johnson Tests of Achievement. (Woodcock & Johnson, 1989). This provided for both validity evidence and analysis of the relationships between PASS and achievement. No further data were available on the CAS when this chapter went to press.

4.08.3 INSTRUMENT INTEGRATION

It is to the advantage of clinical and school psychologists that there are so many instruments available to assess a child's, adolescent's, or adult's intellectual functioning. Often when one instrument is administered, such as the WISC-III or WAIS-R, and then analyzed, the examiner will find that questions and hypotheses are raised regarding the individual's functioning in specific areas. Creativity and a bit of detective work are required to uncover exactly where a person's true deficits and strengths lie in their cognitive abilities. Part of the detective work in this process involves the integration of information from various instruments to support or clarify hypotheses raised as initial results are examined. Thus, examiners ultimately have to be able to integrate data from multiple instruments. As suggested by Kaufman (1994) "crucial educational decisions are sometimes made on the basis of a psychological evaluation, and these decisions should be supported by ample evidence" (p. 326) so that initial hypotheses are verified. This section describes and discusses several cognitive tests in terms of their value when integrated with results from the Wechsler Scales.

4.08.3.1 K-ABC Integration with Wechsler Scales

The K-ABC measures some of the same abilities as the WISC-III and WPPSI-R, but also measures ability in ways that are different from the Wechsler scales, thereby contributing unique information about a child's cognitive functioning. The K-ABC Simultaneous Processing Scale is believed by some researchers to involve the same cognitive requirements as Wechsler's Performance Scale (Das, Naglieri, & Kirby, 1994) and by others to be a measure of Visual Processing (Gv) (Horn, 1991). However, two Simultaneous subtests (Matrix Analogies and Photo Series), involve more reasoning (and load on two of Woodcock's (1990) factors: Fluid Reasoning (Gf) and Visual Processing (Gv)) than Wechsler's Performance subtests: The Sequential Processing Scale of the K-ABC is an excellent addition to the Wechsler because it measures sequential processing more efficiently than any Wechsler subtest. That is, because the only Wechsler test that can be viewed as measuring sequential processing is Digit Span Forward (Das et al., 1994) but the Digit Span subtest score includes Backwards span which involves more than sequential processing (Schofield & Ashman, 1986), there is no efficient measure of sequential processing on the Wechsler. In addition, the K-ABC Achievement Scales are highly related to the Wechsler Verbal IQ and crystallized abilities (Kaufman & Kaufman, 1983; Naglieri & Jensen, 1987).

Given the above characteristics of the K-ABC, examiners may note that the entire Simultaneous Processing Scale serves as a good measure for children with motor and/or speed problems who earn low Wechsler Performance IQs, because it minimizes both of these variables. From the Horn view, the K-ABC offers good supplemental subtests to measure Gc including Faces and Places and Riddles, in the Achievement Scale. These tasks measure range of general knowledge by identifying visual stimuli (Faces and Places), and require the child to use verbal reasoning to demonstrate word knowledge (Riddles). This is unlike many tests, such as WISC-III Vocabulary, and similar Binet IV and DAS tasks, which measure word knowledge by requiring a child to retrieve word definitions from long-term storage. Like the WJ-R crystallized subtests, Riddles requires a one-word response; it is, therefore, a good Wechsler supplement to help discern whether a low V-IQ is due more to conceptual problems or expressive difficulties. The K-ABC offers some alternative modalities of receiving input and expression of response, to supplement Wechsler subtests that mainly use the auditory-vocal and visual-motor channels of communication. The K-ABC offers three subtests which call for use of the visual and vocal modalities (Magic Window, Faces and Places, and Gestalt Closure), and has one subtest that uses the auditory-motor channel (Word Order). In addition, the K-ABC taps the visual and semantic-motor channels with Reading Understanding, which requires a child to read a stimulus and do what it says (i.e., "Stand up").

4.08.3.2 Integration of KAIT with Wechsler Scales

The KAIT was developed from the Horn–Cattell theory and yields both a Crystallized IQ and Fluid IQ. The three subtests comprising the KAIT Fluid Scale are very good supplements to the Wechsler scales. As noted previously, there is controversy regarding how well the Wechsler scales measure fluid abilities; thus, it is wise to administer supplemental tests to tap an individual's fluid reasoning ability and learning ability. Assessment of planning ability, formal operational thought, and learning ability may be obtained through KAIT Fluid Subtests: Mystery Codes and Logical Steps. Problem-solving through verbal reasoning and verbal comprehension is required in Logical Steps, and Rebus Learning demands vocal responding; therefore, the KAIT Fluid Scale measures an ability that is quite different from Wechsler's P-IQ. If questions about an individual's planning speed arise from the primary battery administered, examiners may administer Mystery Codes to further assess planning speed.

To supplement Wechsler's Verbal Scale, the KAIT Crystallized subtests may be used. For assessing an individual's base of general factual knowledge, Famous Faces may be administered to supplement WISC-III or WAIS-R Information. Famous Faces uses pictorial stimuli integrated with verbal clues about famous people; whereas Information is a purely auditory-vocal task. Formal operational thought within the Crystallized domain can be assessed through Double Meanings. Double Meanings challenges examinees to unify apparently disparate semantic stimuli. KAIT subtests, Double Meanings and Definitions, can also provide follow-up to questionable performance on tasks of word knowledge and verbal concept formation, such as Wechsler's Vocabulary or Similarities. Auditory Comprehension can be used for questions regarding an individual's memory and comprehension ability. This subtest mimics a real-life situation, in requiring an individual to listen to a mock news broadcast and answer questions about it. The two delayed recall (TSR) KAIT subtests are also very good WISC-III supplements when hypotheses are raised regarding an individual's memory.

4.08.3.3 Integration of Binet IV with Wechsler Scales

As noted in the earlier discussion of the Binet IV, there is controversial and weak factor-analytic support for the four Binet IV area scores (Verbal, Abstract-Visual, Quantitative, and Short-term Memory). The relationship between Wechsler's Verbal and Performance IQs and the Binet IV Area scores is not clear-cut. In a correlational analysis with the WISC-R and Binet IV (Thorndike et al., 1986), the WISC-R and Binet IV Verbal scales were found to relate substantially to each other. However, Kaufman (1994b) notes that the Absurdities subtest probably lowered the relationship with the Verbal IQ and increased the correlation with the Performance IQ because it uses visual stimuli. In Woodcock's (1990) factor analysis, the Binet IV Quantitative subtests loaded on a separate Quantitative Factor (Gq), which also included Wechsler Arithmetic and WJ-R math achievement subtests. The Binet IV Abstract-Visual subtests, except Matrices, were on the Gv factor, along with most Wechsler Perceptual Organization subtests. Matrices, however, had a substantial loading on the Gf factor; it is, therefore, an excellent addition to Wechsler's Performance Scale.

The Binet IV can be integrated with Wechsler results, and can be especially helpful in assessing young children and mentally retarded individuals because of the extension of its norms down to age two. Response time is relatively unimportant on the Binet IV; therefore, it provides several subtests to further evaluate hypotheses regarding a low score on the WISC-III P-IQ or PO Index. If poor fluid intelligence is suspected, Pattern Analysis, Paper Folding and Cutting, Matrices, and Number Series can be administered. To further assess the comprehension knowledge ability measured by the WISC-III, without requiring verbal comprehension, Absurdities is especially good to administer because the stimulus is visual and minimally verbal. For assessing whether a child's fluid reasoning ability generalizes to number manipulation activities, the two Binet IV Quantitative subtests are useful. The tasks not included on the Wechsler scales such as Matrices, Equation Building, Number Series, and Verbal Relations, can be used to further explore the reasoning abilities of an individual.

4.08.3.4 Integration of WJ-R with Wechsler Scales

Wechsler's Verbal IQ primarily can be viewed as a measure of crystallized intelligence and short-term memory; Performance IQ as a blend of fluid reasoning, visual processing, and processing speed (Kaufman, 1994b). However, some researchers view Wechsler's Perceptual Organization to be a measure of visual processing (McGrew & Flanagan, 1996; Woodcock, 1990). Long-term retrieval is not specifically measured by the Wechsler scales nor is auditory processing. And, if Woodcock and others are correct, then fluid reasoning also is not measured very well by the Wechsler scales. Therefore, WJ-R Cognitive subtests provide excellent tasks for extending assessment from Wechsler subtests using the WJ-R tests which were developed to reflect Horn's pure factors. The WJ-R provides subtests which are controlled learning tasks, allowing the assessment of a person's learning ability. Conventional intelligence tests, including Wechsler's, do not typically measure this ability. The controlled learning subtests include the following: Memory for Names and Visual–Auditory Learning (both Long-term Retrieval tasks), and Analysis–Synthesis and Concept Formation (both Fluid Reasoning tasks). Whereas the Wechsler Performance subtests emphasize visual-motor coordination and speed of response, Analysis–Synthesis and Concept Formation involve no motor coordination at all, and speed of response is not a major variable in determining a person's performance level.

The WJ-R provides several subtests from which to choose, so when questions arise regarding Wechsler's Perceptual Organization construct (including visual processing and fluid abilities, as noted above), the WJ-R is an excellent tool to investigate these hypotheses. The different aspects of the information-processing model are measured by four WJ-R factors including Gv (input), Gf (integration), Glr (storage), and Gs (output). A high or low score on Wechsler's Performance scale should be explored further to determine what aspects of an individual's information-processing may have affected this asset or deficit. If an individual is suspected of having a deficit or strength in their nonverbal visual-spatial ability, requiring further testing for clarification, then WJ-R Spatial Relations is a useful tool to make that determination. The other Fluid Reasoning subtests, previously mentioned, have a heavy verbal component and do not assess visual-spatial skills, although they do use figural material. (One precaution to note is that cognitive tests in the WJ-R battery are heavily entrenched in the tradition of measuring intelligence through predominantly verbal means (Kaufman, 1990)).

For assessing strengths or weaknesses within the auditory-vocal channel, the following WJ-R factors may be used: Ga (input), Gc (integration), and Gsm (storage). These factors can be helpful in clarifying questions raised in the Verbal scale of the Wechsler test. On the WJ-R, two Gc tasks require one-word responses, which make them good when you do not know if a low Verbal score reflects poor concepts or poor expression. Auditory-perceptual tasks on the Ga scale assess whether a child can perceive words in isolation (through filling in the gaps or by blending sounds). However, for assessing a processing deficit of longer auditory input, additional subtests may be needed (such as the Cognitive Assessment System subtests Verbal-Spatial Relations, Sentence Repetition, and Sentence Questions).

Wechsler scales do not assess long-term memory over the period of a few minutes, although they do measure short-term memory with Digit Span and remote memory with Picture Completion and Information. The Long-term Retrieval subtests of the WJ-R provide a good assessment of the long-term memory function; therefore, these tasks complement the Wechsler subtests for supplementary analysis. In addition, the WJ-R tests provide a measure Auditory Processing and Visual Processing, which have strong perceptual components. These perceptual processes are not typically evaluated in most tests of intelligence, but need to be assessed in cases with possible neuropsychological difficulties.

4.08.3.5 DTLA-3 Integration with Wechsler Scales

The DYLA-3 has several theoretical underpinnings, including models such as fluid and crystallized intelligence, simultaneous and successive processes, and verbal and performance abilities. DTLA-3 subtests may be used to augment the Wechsler scales in several instances. To further assess perceptual organization ability, fluid ability, and simultaneous processing, Design Reproduction or Symbolic Relations may be administered. For hypotheses regarding similar fluid abilities, but tapping sequential processing, examiners may administer Design Sequences. DTLA-3 Design Reproduction is also a good supplement Wechsler Performance subtests if there is a question regarding a person's ability being hampered by response speed tests. This test does require visual-motor coordination but places minimal demands on speeded performance. Like the K-ABC, the DTLA-3 offers some alternative modalities of receiving input and expression of response to supplement Wechsler subtests that mainly use the auditory-vocal and visual-motor channels of communication. The DTLA-3 offers two subtests which call for use of the visual and vocal modalities (Story Construction and Picture Fragments), and has one subtest that uses the auditory-motor channel (Reversed Letters).

4.08.3.6 Integration of DAS with Wechsler Scales

The six Core subtests of the DAS create three separate scales for children, namely: Verbal, Spatial, and Nonverbal Reasoning. The WISC-III Verbal Comprehension subtests (specifically Vocabulary and Similarities) have been noted to be quite similar to the DAS Verbal Scale (Kaufman, 1994). The DAS Verbal, Spatial, and Nonverbal Reasoning scales have been shown to correspond to the Woodcock–Johnson Revised factors of Gc, Gv and Gf, respectively (McGhee, 1993).

The two subtests comprising the DAS Nonverbal Reasoning Scale provide an excellent addition to the WISC-III because they are quite different from WISC-III subtests. The Nonverbal Reasoning subtests (Matrices, and Sequential and Quantitative Reasoning) measure nonverbal reasoning without time limits but they do require visual-motor coordination, and minimize visualization. Thus, they can provide good measures of an individual's pure fluid ability. DAS subtests requiring visual-motor coordination, but placing minimal demands on speeded performance include Recall of Designs and Pattern Construction (when the latter test is administered via special procedures). Thus, these subtests can be useful in following up hypotheses generated from Wechsler's Performance subtests, which reward quick performance.

4.08.3.7 Integration of CAS with Wechsler Scales

Like the other tests included in this chapter, the CAS has some overlap with the WISC-III, but because its conceptualization is based on the PASS theory unique information about a child's cognitive functioning can be obtained. The CAS Planning and Attention Scales require processes that can not be effectively assessed by the Wechsler Scales (Das et al., 1994). In order to measure planning adequately, tests that evaluate the child's ability to decide how to solve problems, and determine their effectiveness are required. This means that the child must be given the opportunity to compete tasks in planful ways, unencumbered by rules imposed by the test. Additionally, items that are influenced by the child's plan rather than other factors (e.g., spatial or verbal skills) are needed. Tests of this type are not found on the WISC-III. Attention tests should demand the focus of cognitive activity and selective attending to particular information while avoiding distraction. Carefully constructed measures of attentional processes are not included on the Wechsler, yet this, as well as planning processes, are especially important when evaluating children, especially those with attention deficits and learning disabilities, for example. The measurement of Planning and Attention offer important cognitive functions that extend beyond the WISC-III and therefore offer additional information for diagnosis as well as intervention (Das et al., 1994).

The CAS, like the K-ABC, provides a measure of simultaneous processing that is similar to the demands of Wechsler's Performance Scale (Das et al., 1994) but there are important distinctions. The CAS offers a verbal test of simultaneous processing (Verbal-Spatial Relations), one that involves memory (Figure Memory), and one with complex demands (Nonverbal Matrices). The addition of the Verbal-Spatial Relations subtest is important because it integrates both nonverbal and verbal stimuli for the comprehension of logical grammatical sentences. Similarly, the Successive processing Scale of the CAS provides tests that demand immediate recall of information (Word Series), and also measures that demand comprehension of syntax (Sentence Repetition and Setence Questions) and where the involvement of immediate memory is markedly reduced (Successive Speech Rate).

The CAS offers a view of ability that reduces the influence of language and achievement, and therefore, provides additional information from the WISC-III or the WPPSI-R to evaluate the performance of children who are bilingual or whose educational history is problematic. Because the CAS does not have achievement or language based tests like the Wechsler (e.g., Arithmetic or Vocabulary) the reduction in the involvement of acquired knowledge provides an opportunity to evaluate children whose poor school history or language difference may have lowered their Wechsler scores. In such a situation the CAS scores can assist the psychologist in determining the extent to which low Wechsler scores may reflect language/achievement issues rather than low intellectual ability.

4.08.4 FUTURE DIRECTIONS

Intellectual assessment has changed a great deal in the twentieth century. It has moved from assessments based on language and speech patterns to sensory discrimination, with most early assessments being for the mentally deficient. Gradually, the assessment instruments developed into the precursors of the standardized instruments used in the 1990s, which measure more complex cognitive tasks for all levels of cognitive ability. The most commonly used tests, the Wechsler scales, were not developed out of theory, but were guided rather by clinical experience. In the progression of test development, the relative alternates to the Wechsler have been more theory-based. The direction in test development in the 1990s seems to be continuing to lead to theory being at the base of intelligence tests, instead of being just purely clinically driven. Psychometric theories and neurological theories are growing as the basis for new instruments. However, despite this proliferation of new theory-driven tests, there is a definite conservatism that holds on to the past, reluctant to let Wechsler tests be truly rivaled. Part of this hold on the past is research-based and part is clinically-based. Because the Wechsler tests have been reigning supreme for so long, there has been a mountain of research studies using the Wechsler scales. Thus, clinicians have a good empirical basis to form their understanding of what a specific Wechsler profile may be indicating. Clinically, psychologists are also quite comfortable and familiar with the Wechsler scales. A good clinician who has done many assessments may be familiar enough with every nook and cranny of the WAIS-R to barely need the manual to administer it. Thus, the field so far has changed relatively slowly. Computer based technology is likely going to ultimately shape the field of assessment by 2020. Computer scoring programs and computer assisted reports are already in use, and the future is likely to include a much greater progression of technologically advanced instruments for assessing intelligence.

4.08.5 SUMMARY

This chapter first introduces the assessment of intellectual ability through a brief overview of its development throughout history. Some important faces in the history of assessment include those such as Jean Esquirol, Edouard Seguin, Sir Francis Galton, James McKeen Cattell, Alfred Binet, Lewis Termin, and David Wechsler. The early pioneers in assessment focused mainly on tests for the mentally deficient, but more recently in history tests were developed for assessing all levels of intellectual functioning. The progression of test development to the standardized instruments we know today is reviewed in the beginning of this chapter.

The debate over intelligence testing is also discussed in this chapter. Three groups of critics are presented. One controversy is raised by those opposed to subtest interpretation advocated by Wechsler; another is those that insist that all the Wechsler scales measure is *g*, rendering the different scales meaningless; and a final controversy is raised by a group who complains that the instruments do not enhance remedial interventions. Kaufman's (1979, 1994b) intelligent testing approach is presented in response to the criticism. The aim of the basic principles of intelligent testing presented in this chapter is to encourage clinicians to approach the task of profile interpretation using their knowledge of research, theory, and clinical skills, rather than being overly dependent on specific scores.

With this important philosophy of intelligent testing in mind, 10 measures of child, adolescent, and adult intelligence are discussed. The Wechsler scales are generally used by examiners as the primary instrument in an assessment battery. However, there are multiple other excellent instruments available for assessing cognitive ability. The following instruments are discussed: WPPSI-R, WISC-III, WAIS-R, K-ABC, KAIT, Binet-IV, WJ-R Tests of Cognitive Ability, DTLA-3, DAS, and CAS. For each, the theory or theories underlying the instrument is presented, followed by the standardization and properties of the scale, including research using the scale, and each is completed with an overview of the instrument.

One of the main principles of the intelligent testing philosophy discussed is that hypotheses generated from the profile of the main assessment instrument should be supported with data from multiple sources. Accordingly, this chapter discusses how to supplement the Wechsler scales with additional cognitive tasks to support or clarify hypotheses raised from the initial cognitive battery. It is important for examiners to be knowledgeable and insightful in choosing supplemental measures to uncover exactly what an individual's cognitive strengths and weaknesses are, in order to form the basis for good recommendations. Specific examples are given for how examiners may supplement the Wechsler scales with each cognitive instrument presented. For example, hypotheses raised in the Wechsler profile regarding fluid reasoning may be further assessed by WJ-R subtests or KAIT subtests. If questions arise regarding the effect of response speed, the Binet IV or K-ABC Simultaneous subtests may be useful supplements. The DAS provides good supplemental information about nonverbal reasoning ability. Alternative modalities of receiving input and expression of response may be assessed by the DTLA-3 or K-ABC subtests. The K-ABC Achievement subtests may also provide additional information about an individual's verbal ability or crystallized abilities. Unique information about a child's planning ability may be found by supplementing a battery with the CAS. The multiple pieces of evidence provided by the supplemental tests, can be carefully integrated to confirm or deny hypotheses raised in an individual's cognitive profile. An illustrative case report is presented at the conclusion of this chapter, which provides an example of how many different sources of evidence are combined to provide a clear description of a 13-year-old female's cognitive and academic functioning.

The future direction of intellectual assessment appears to be in theory-driven instruments. The psychological community has held tightly onto the clinically-based Wechsler scales because of their large research base, clinical familiarity, and just tradition. Thus, psychometric and neurological theories are becoming an important base for the newer instruments of assessment, although their use by the majority of clinicians has only slowly been occurring. Technological advances are also eminently going to be further impacting the field of assessment. The use of computer science and neurological measurement will likely begin to change the face of cognitive assessment within the next few decades.

4.08.6 ILLUSTRATIVE CASE REPORT

The following case report is of Laura S., a 13-year-old seventh grader, experiencing difficulty on standardized tests in the areas of vocabulary, reading comprehension, and writing mechanics. This report illustrates the methods and procedures for test integration and interpretation described earlier in this chapter. Table 12 provides the specific scores earned by Laura on each instrument administered.

4.08.6.1 Referral and Background Information

Laura was brought in for an evaluation by her parents, Linda and Rob (Mr. & Mrs. S) who were referred for an assessment by her current school, due to concern about the inconsistency between Laura's high grades at school and her lower standardized test scores in some areas. From Laura's scores on the Educational Record Bureau's (ERB) Comprehensive Testing Program (CTPII), the main area of concern to Laura's parents was in her Verbal Ability, specifically, Vocabulary, Reading Comprehension, and Writing Mechanics. Mr. and Mrs. S. would like to gain a better understanding of Laura's difficulty with her mathematics courses, reading comprehension, and memory retention. Laura's parent's reported that she does not always seem to understand written instructions and asks a lot of questions. They would specifically like recommendations to help Laura improve her learning ability, enhance her memory, and develop a greater aptitude for understanding directions.

Laura is a 13.5-year-old adolescent girl who has lived at home with her mother and step-father since age three. At age 2.5., her mother and biological father separated, and, other than for one month of her life, she has lived with her mother. Laura also has a 20-year-old step-sister, Kelly, and a 23-year-old step-brother, Rick, who do not live with her at home. Mr. and Mrs. S. both work full-time as professionals outside the home. Laura's biological father lives out of state and Laura visits him once or twice a year. Laura has also had other adults serve as caretakers for her. From ages 1–3, her mother indicated that two other people helped care for her, and from ages 4–13, five housekeepers also provided care for her.

Mrs. S. reported that she had a normal, full-term pregnancy with Laura. There were no problems during the birth, and Laura was born weighing six pounds, nine ounces after a short labor of only 15 minutes. Laura's medical history is relatively unremarkable, with her parents noting only that she experienced a bilateral hernia at nine months and had several earaches and colds as a younger child. Mr. and Mrs. S. stated that their daughter has never been hospitalized, has had no major injuries, or diseases. All of Laura's developmental milestones were "on time" or "early" according to her mother.

A medical question of Laura's parents had been her hearing ability, due to her noted difficulty sometimes distinguishing particular sounds in school and occasional single-word substitutions. After discussing this at the current evaluation's intake interview, Mr. and Mrs. S. took Laura to a physician at a local university's Medicine Ear Institute to rule out any potential hearing loss. According to a letter sent by the physician, he performed a physical exam and audiogram for Laura. He stated that her audiogram "revealed normal thresholds bilaterally with excellent speech discrimination," and "she appears to have normal hearing."

Laura's educational history began when she entered preschool at age three. According to her parents, she had no difficulties with beginning preschool or transitioning to her next school. All of Laura's report cards from first through seventh grades indicate consistent, excellent achievement. Most of her teachers commented on her conscientious and serious approach to learning, and express their great pleasure having her as a student.

A classroom observation of Laura was performed for this evaluation. Laura was observed in her Honors math class. Laura was very friendly, chatting with her friends and brightly greeting the teacher right before class. However, as soon as the class began, she got right to work. When the instructor asked questions of the class, Laura raised her hand to every question. She was focused on the work all throughout the class, and seemed motivated to do well in math. She asked the teacher for assistance several times during the observation. In an interview, the teacher stated that Laura frequently asks for extra help, but it is her teacher's belief that this is mainly because "she

does not trust her gut." The teacher said that Laura always begins the class with a happy, cheerful mood, but she tends to "stress out" when problems become difficult.

In discussing family history related to Laura's difficulties, Mrs. S. indicated that she feels she also has "a poor memory and retrieving skills." Mr. and Mrs. S. noted that Laura has several strengths, including her strong intuitive abilities, her confidence, and her persistence. Laura is very popular with her peers and is viewed as a leader by many of her teachers.

In an interview with Laura, she stated that she does not enjoy reading but likes using her creativity in writing. She said that she takes school more seriously than most of her peers, and has set very high standards for herself. She explained that she is harder on herself than her parents are, especially when it comes to academics. In her free time Laura works diligently on her homework and enjoys playing tennis and soccer, and socializing with her friends.

4.08.6.2 Appearance and Behavioral Characteristics

Laura is a mature, pretty, 13-year-old seventh grader. She wore her thick brown hair parted stylishly down the middle. For each of the evaluation sessions she dressed casually and neatly in jeans and a sweatshirt. She talked comfortably when asked questions by the examiner and spoke in soft voice with an air of politeness and good manners. She tended to respond with short phrases rather than in complete sentences when answering questions posed by the examiner. However, this did not detract from her ability to articulate her thoughts clearly.

She seemed eager to please the examiner, often asking for clarification about what was the right thing to do during a certain subtest. For example, during a task which required her to look at a picture and tell what important part was missing, she asked, "Can I tell you what's wrong with it?" Her frequent questions to the examiner indicated not only her anxiousness to please, but also her uncomfortableness with ambiguity in a situation. She appeared much more relaxed when the situation was structured and she knew clearly everything that was expected of her.

Laura demonstrated a strong ability to concentrate and focus. She had great stamina throughout the mentally challenging evaluation. She was persistent in always refusing breaks offered to her and worked straight through during each session, displaying extreme self-control. She was cooperative and friendly, often helping the examiner put away stimulus materials and always following directions. Encouragement from the examiner was welcomed warmly with a smile by Laura. She gradually became less cautious in her casual conversation with the examiner as the testing progressed. She began to share bits and pieces of her life and showed a well-rounded self.

Laura always tried her best. Even after having attempted problems that were difficult for her, she did not lose her motivation to keep trying. In solving problems she worked quickly, but was reflective. She would continue to check her work, even after she was done, always being careful in her responses. Laura expressed anxiety about having to solve mathematical problems mentally, saying, "I can't do things in my head, without pencils and things." She was more tentative in answering such questions. On more difficult nonverbal tasks, Laura tended to analyze the situation first and then proceed with the task. Again, evidence of her trying carefully to do her best and not make mistakes. On the basis of her behavior during the evaluation these results should be considered a valid representation of her ability.

4.08.6.3 Tests Administered

(i) Wechsler Intelligence Scale for Children-3rd edition (WISC-III)

(ii) Woodcock–Johnson-Revised (WJ-R): Tests of Achievement

(iii) Kaufman Adolescent and Adult Intelligence Test (KAIT): Fluid Subtests

(iv) Rotter Incomplete Sentences.

4.08.6.4 Test Results and Interpretation

Laura was administered a series of cognitive tests to assess her information processing abilities. According to the WISC-III, Laura is functioning currently within the Average to High Average range of intelligence. She obtained a Verbal IQ score of 114 ± 5 (82nd percentile), Performance IQ score of 95 ± 5 (37th percentile), and Full Scale IQ score of 106 ± 4 (66th percentile). In addition, she also obtained a Verbal Comprehension Index of 120 ± 5, which was significantly higher than her Freedom from Distractibility Index of 101 ± 8. However, this difference within her verbal scale was due mainly to her difficulty computing arithmetic problems mentally. Laura's Processing Speed Index of 111 ± 7 was significantly higher than her Perceptual Organization Index of 94 ± 6, indicating that she performed better on tests of visual processing speed than on tests of nonverbal reasoning.

It is important to note that Laura's Verbal subtest scores exhibit a significant amount of scatter, suggesting that her Verbal Comprehension and Perceptual Organization Indices provide a more meaningful picture of her abilities than the overall Full Scale IQ, Verbal IQ, or Performance IQ. The variance in her Verbal Scale indicates that some of her abilities are more well developed than others. The difference between her verbal and nonverbal abilities, as reflected by her Factor Indices, is unusually large and statistically significant. Because there is a 26-point difference in favor of her Verbal Comprehension Index over her Perceptual Organization Index (occurring in less than 5% of normal children), her Full Scale IQ should not be used as an indication of her overall ability. A fuller and clearer picture of Laura's abilities can be found by looking at her performance in individual areas rather than considering the statistical average of these various abilities.

In the verbal area, Laura demonstrated a significant weakness in Arithmetic, earning a score in the 25th percentile. The WISC-III arithmetic does not allow use of paper and pencil to do computation, so Laura was required to manipulate the numbers mentally to solve auditorally and visually presented problems. She expressed several times during this test that she needed to see the numbers and have them down concretely in front of her to figure the problems out. Her weakness on WISC-III Arithmetic was in contrast to her higher scores in the mathematics area on Woodcock–Johnson-Revised Tests of Achievement (WJ-R). All of the mathematics on the WJ-R allowed the use of paper and pencil in solving the problems, which Laura was more comfortable with. Her performance on problems of calculation, such as addition, subtraction, multiplication, and division with multiple digit numbers, decimals, and fractions, was significantly better than her performance on applied problems requiring her to use mathematics to solve problems involving scenarios with money, distance, and weight. On the Woodcock–Johnson-Revised Mathematics Subtests, she scored at the 86th percentile on calculation and 56th percentile on problems that were applied. Thus, her weakness in Arithmetic on the WISC-III is not due to poor computation ability, but rather due to the fact that she needs the concrete visual stimulus of written numbers in order to utilize the mathematical knowledge that she does have.

Laura's variability in her performance on the Verbal Scale of the WISC-III was accentuated by her extremely high score (99th percentile) on a test of social judgment, verbal reasoning, and practical knowledge. Her strong verbal ability was apparent during this subtest, as well as on a subtest requiring her to use abstract reasoning to describe how two things are similar. This strength was also paralleled by her excellent performance on WJ-R tests of written expression, on which she earned an overall score at the 98th percentile. She can come up easily with vocabulary to express her ideas and is able to formulate alternative ways to get her point across if it is unclear. However, the mechanical details of written expression are more difficult for Laura. For example, she earned a lower score on a test of dictation (37th percentile), which examined her spelling, punctuation, and word usage. Laura's performance in spelling, punctuation, and word usage was at a lower level than her overall Written Expression ability (41st, 50th, and 44th percentiles, in contrast to 98th percentile). Thus, she is able to get her verbal ideas across, but is lacking skill in the grammatical rules and details of written expression.

Laura's verbal reasoning ability also appeared stronger than her knowledge of general factual knowledge. She scored at the 63rd percentile on a WISC-III task requiring her to answer questions about information acquired from to formal schooling. However, her performance on WJ-R tests of Broad Knowledge was lower than expected, given her high level of academic achievement at school, as well as her performance on other WJ-R tests of achievement. On subtests covering areas such as science, social studies, and humanities, Laura scored in the Average level at the 48th percentile. A person with Laura's total achievement performance would have been expected to earn a slightly higher score on these tests of Broad Knowledge. Her actual standard score was 1.2 standard deviations lower than what was predicted in this area, indicating that she is not achieving at a level consistent with what would be expected given her level of achievement. This is also reflected in her lower ERB group standardized test scores that are discrepant from her higher school grades. The ERB scores reflect strictly facts derived from multiple choice exams. However, her interaction with teachers, participation and performance at school allow the teachers to understand Laura as a more complete person, which positively influences her grades.

Laura's performance on WJ-R Broad Reading (89th percentile) is also commensurate with her strong verbal reasoning skills evidenced. However, her score on a task measuring comprehension of a written passage was somewhat lower than expected (65th percentile) given her strong verbal abilities. Nonetheless, it is in the average range and not low enough to be of concern. Overall, Laura's strong performance on Broad Reading ability was 1.48 standard deviations above what would be predicted for an individual with her total achievement performance, so she is demonstrating strong ability with her reading skills. Only 7% of students Laura's age, who had the same expected standard score as she, scored as high or higher than Laura on Broad Reading Subtests of the WJ-R.

Laura's significantly higher score on the Verbal Comprehension Index than the Perceptual Organization Index of the WISC-III indicates that her verbal abilities are more well developed than her nonverbal and perceptual abilities. However, even on the nonverbal performance tests, all of her scores were at or above the Average level (25th to 91st percentiles). For example, Laura performed well on a task requiring her to use short-term memory in copying a series of different symbols from a visually presented key. She scored at the 91st percentile on this task and scored at the 63rd percentile on a another nonverbal task requiring her to reproduce a model using blocks.

Her cognitive skills were further assessed by the Fluid Scale of the Kaufman Adolescent and Adult Intelligence Test (KAIT). The KAIT Fluid subtests measure one's ability to solve novel problems using reasoning, memory, paired-associate learning, verbal comprehension, and perceptual organization. Laura scored well above average (standard score 120 ± 5) on these tasks involving her ability to solve novel problems. She scored at the 98th percentile on a task that essentially required her to learn a new language through paired-associate learning. On this task she used her good verbal concentration, expression ability and memory to succeed. She also performed quite well on tasks that required her to use abstract reasoning with novel stimuli and planning ability.

4.08.6.5 Summary and Diagnostic Impressions

Laura is a mature, pretty 13-year-old girl who was brought in for a psychoeducational evaluation by her parents due to their concern with inconsistency between her standardized tests scores and high grades at La Jolla Country Day School. Her parents' main areas of concern involve her abilities in vocabulary, reading comprehension, writing mechanics, and mathematics. Mr. and Mrs. S. wanted a better understanding of these discrepancies in her performance, as well as her difficulty with memory retention and understanding written directions.

Laura demonstrated strong motivation to please the examiner, persistence, and stamina during her evaluation. She was reflective in her problem solving and careful in her responses, trying hard to perform to the best of her ability. She earned scores in Average to High Average range of intelligence on the WISC-III. Her factor indices and specific strengths and weaknesses gave the most meaningful picture of Laura's abilities, due to the scatter in her verbal subscales. She performed significantly better on tests of verbal reasoning and word knowledge than on tests of nonverbal ability and visual-perceptual skills. She demonstrated a weakness on a task requiring her to mentally solve auditorally and visually presented arithmetic problems. However, this was due to her difficulty performing mathematical calculations in her head without the concrete visual help of pencil and paper, as evidenced by her higher scores on WJ-R tests of Mathematics that allow use of pencil and paper for problem-solving.

Her strengths were in the area of verbal reasoning. This was congruent with her strong ability to express herself in a written format on the WJ-R and also with her overall reading ability demonstrated on the WJ-R. Although her ability to express herself verbally and in writing was good, her skills in the details of writing, such as spelling, punctuation, and usage were not as strong. In addition, her performance on a test of passage comprehension was not as high as expected given her overall verbal abilities. In the area of general knowledge, including science, social studies, and humanities, Laura did not perform as well as one would predict given her other achievement scores.

On an additional cognitive test measuring Laura's ability to solve novel problems, she demonstrated well above average abilities. On the KAIT Fluid subtests, Laura's performance indicated that she has strong ability to learn new material through paired-associate learning. She also evidenced above average ability to use abstract reasoning and planning ability with novel stimuli.

Laura has learned very well to compensate for her areas of weakness, which is evident in her high grades at school. Her ability to ask questions when uncertain, and create a structured environment for herself so she is most comfortable are examples of such compensatory strategies. Additionally, this strength is reflected in her higher grades at school compared to her ERB scores. Her ability to express herself well in writing and vocally, such as on essay tests or class discussions, helps her grades at school but is not able to aid her in the cut-and-dry responses needed for the ERB tests. Her strong ability to solve novel problems will be quite useful to Laura in continuing to creatively create other strategies when new difficulties appear in her life.

4.08.6.6 Recommendations

The following recommendations have been made to assist Laura and her parents in enhancing her learning ability.

(i) Laura is a highly self-motivated student who has created very high expectations for herself, and has been working very hard to meet those high standards. At times this causes anxiety for her, and when this anxiety reaches an unmanageable level it may cause difficulty and decreased performance. It will therefore be useful for Laura and her parents to discuss that it is okay not to be perfect in every area of her life, every minute of the day, and to allow Laura to experience those instances of nonperfection. Tolerance and appreciation for her own continuum of strengths to weaknesses needs to be developed to keep Laura feeling good about herself.

(ii) As Laura works so hard at not making any mistakes, she is sometimes hesitant to proceed without asking many questions to prevent making any sort of error. She demonstrated strong abilities in many areas and therefore should be encouraged to go with her gut feeling, and try to attempt problems that normally she may immediately ask for help on. This will further foster her sense of independence and confidence in her own abilities.

(iii) Laura expressed being uninterested in some subjects that have not stressed problem-solving or reasoning as learning methods, such as Social Studies. If her school classes present material in a factual, "memorize this" style, then Laura needs to study in more creative way to enhance her learning and reduce boredom. For example, she can make up a story about a character that may have lived in a period of history that she is learning about. As another example, Laura can draw and illustrate a timeline of important historical events to remember.

(iv) To incorporate a different method of studying subjects that are especially tedious to Laura, she could study with another diligent student. Similarly, she may want to get together with a group of peers and create a quiz show to reinforce and study facts that may seem boring to her when she is studying alone.

(v) To encourage her to become comfortable with and reinforce information that may be presented in a test format such as the ERB tests, Laura may create a competition for herself. For example, on a weekly basis she could give herself a test on a content area (such as those in books created for SAT preparation), and then she could chart her own progress from week to week.

(vi) It is important to reassure Laura that it is fine to use the compensatory strategies that work for her, such as writing down arithmetic problems. Her ability to figure out such strategies is a strength that was evident in her ability to solve novel problems and can be used to help her in areas that are more difficult for her.

(vii) To help Laura increase her overall academic abilities, Laura will benefit from broadening her base of what she considers "studying." Studying includes not only completing assignments given at school and preparing for exams, but also includes an awareness of one's environment outside of the school context. In broadening her conceptualization of studying, for example, Laura may incorporate more pleasure reading of nonschool books or magazines into her weekly routine, which will benefit her grammar and vocabulary. She may watch a movie or television program and relate it to some topic she is studying in school. This is important as people who improve their general learning, tend to do better overall on standardized types of testing.

(viii) Laura demonstrated strong written expression ability, but weaker ability to incorporate correctly details of grammar such as spelling and punctuation. These details may be less interesting to Laura, thus, again she may want to use her problem-solving ability to create more interesting ways to learn such details. There are many excellent computer programs that help teach grammatical details, in an interesting manner. As Laura tends to strive for excellence, she may set goals for herself according to a computer program she is working with to help her.

(ix) Laura is very conscientious and focused in her school work. She may benefit and find it rewarding to become a peer tutor for a lower grade child (such as a fourth- or fifth-grade student). Tutoring a child who is having trouble with grammar will reinforce rules in Laura's mind as she gains self respect by being appointed to teach someone else.

ACKNOWLEDGMENTS

The authors would like to thank Drs. Kristee A. Beres, Randy Kamphaus, Nadeen L. Kaufman, Jack A. Naglieri, and Mitch Perlman for their contributions to this chapter.

4.09.1 INTRODUCTION

The inner workings of the human mind and the way in which people process information has intrigued researchers for centuries. The traditional categories of cognition, such as attention, memory, language, and learning are terms frequently used and considered all important to our daily adaptive functioning and ability to learn new information. Yet all have defied simple explanation and manipulation (e.g., Gaddes & Edgell, 1994; Lezak, 1995). That is, as professionals we are able to identify when a child or adult is having difficulty processing information, but the exact interrelations between an individual's different capacities in areas such as attention, learning style, and sensory integration still eludes educational and clinical specialists. More puzzling still is finding effective rehabilitation strategies to address deficits in memory, learning, and other psychological processes. These areas are frequently addressed in the growing volumes of neuropsychological research, but are relevant to the practices of many traditionally trained psychologists as well (Hamsher, 1984). Not surprisingly, all of the information needed for an adequate understanding and interpretation of cognitive processes cannot be provided in a single chapter or obtained in an individual university course. Thus, the purpose of this chapter is to provide a brief description of our higher cognitive processes and introduce a variety of strategies and measures for evaluating these functions.

Problems in attention, memory, and learning are not isolated to the very young or the very old. Adult learning problems often become apparent in employment settings and after injuries resulting from strokes, accidents, or diseases. Epidemiological studies suggest that in the decade following the late 1990s there will be a dramatic increase in the number of individuals suffering from organically related disorders resulting from the abuse of alcohol and other types of toxic substances (Touyz, Byrne, & Gilandas, 1994). The recent documented increase in the number of head injuries caused by motor vehicle accidents has become an intrinsic fact in today's society. High speed transportation and the growing prevalence of violent street crimes have further increased the incidence of head injuries (Touyz et al., 1994). So too, the growing popularity of certain contact sports (e.g., hockey, boxing), noncontact sports (e.g., rock climbing, mountaineering, bicycling), and recreational activities (e.g., skateboarding, roller blading) has contributed significantly to the number of individuals suffering from traumatic brain injury (Drew & Templer, 1992; Templer & Drew, 1992). Internal processes such as eating disorders, depression, diseases, epilepsy, and tumors can result in impaired executive functioning as well (Black & Strub, 1994). These realities of today's society make it necessary for clinicians to be able to accurately evaluate a client's strengths and weaknesses in everyday functioning and find the key elements to fostering effective behavioral change through rehabilitation or educational improvement.

Psychology has made many new inroads into understanding the learning process and the subsequent development of corrective or adaptive programs for children and adults with learning disorders and traumatic brain injuries. As assessment specialists, psychologists must quickly and accurately wade through the cumulative data available about the individual in order to select the most viable of alternative hypotheses to explain the findings and offer appropriate interventions (D'Amato & Dean, 1989a; D'Amato, Rothlisberg, & Leu, in press; Gutkin & Reynolds, 1990). Although administering a test may be a routine activity, conducting a thorough, valid assessment is an extremely complex process. The clinician is required to make decisions regarding which skills to evaluate and the best instrument to use with a particular client, and to generate accurate interpretations of the results in order to create the most effective intervention plan. Adding to the immensity of this task are the wide range of client variables that can impact the assessment process, including motivation, environment, culture, age, developmental level, language, training, educational quality, personal experience, and attitude to name just a few (Golden, Sawicki, & Franzen, 1984; Hynd & Semrud-Clikeman, 1990).

The clinician must recognize that the context of the client may influence or even define the outcome of the assessment (Dana, 1993; Figueroa & Garcia, 1994). For example, many of the psychological, educational, and personality instruments available to practitioners have been criticized as culturally biased, as traditionally not including individuals from diverse ethnic backgrounds in the norming sample, and as measuring acquired knowledge rather than an individual's responsiveness to instruction or the learning process (Cole & Siegel, 1990; Dana, 1993; Figueroa & Garcia, 1994; Sattler, 1992). Because of these problems, several researchers believe that standardized assessment may have questionable validity for those clients who represent diverse cultural groups (Cole & Siegel, 1990; Dana, 1993; Figueroa & Garcia, 1994; Martinez, 1985). From the beginning, one robust assumption of standardized testing was that all individuals who take the tests would have had equal or comparable exposure to the contents of the assessment materials prior to the assessment (e.g., Colvin, 1921; Dearborn, 1921; Woodrow, 1921). In direct contrast to this supposition, current statistics indicate that the US immigrant population is not only growing rapidly but is also quickly expanding in diversity (Figueroa & Garcia, 1994). These authors conclude that tests, although given high status in US society, are actually quite fragile because of the founding assumption regarding homogeneity and general shortcomings in technical properties. Nevertheless, standardized tests can be useful in evaluating current functioning especially when multiple sources of information and multidimensional functions are evaluated to measure individual processes (Sattler, 1992). The responsible clinician must recognize both the assets and the limitations when using standardized measures with ethnic minority clients.

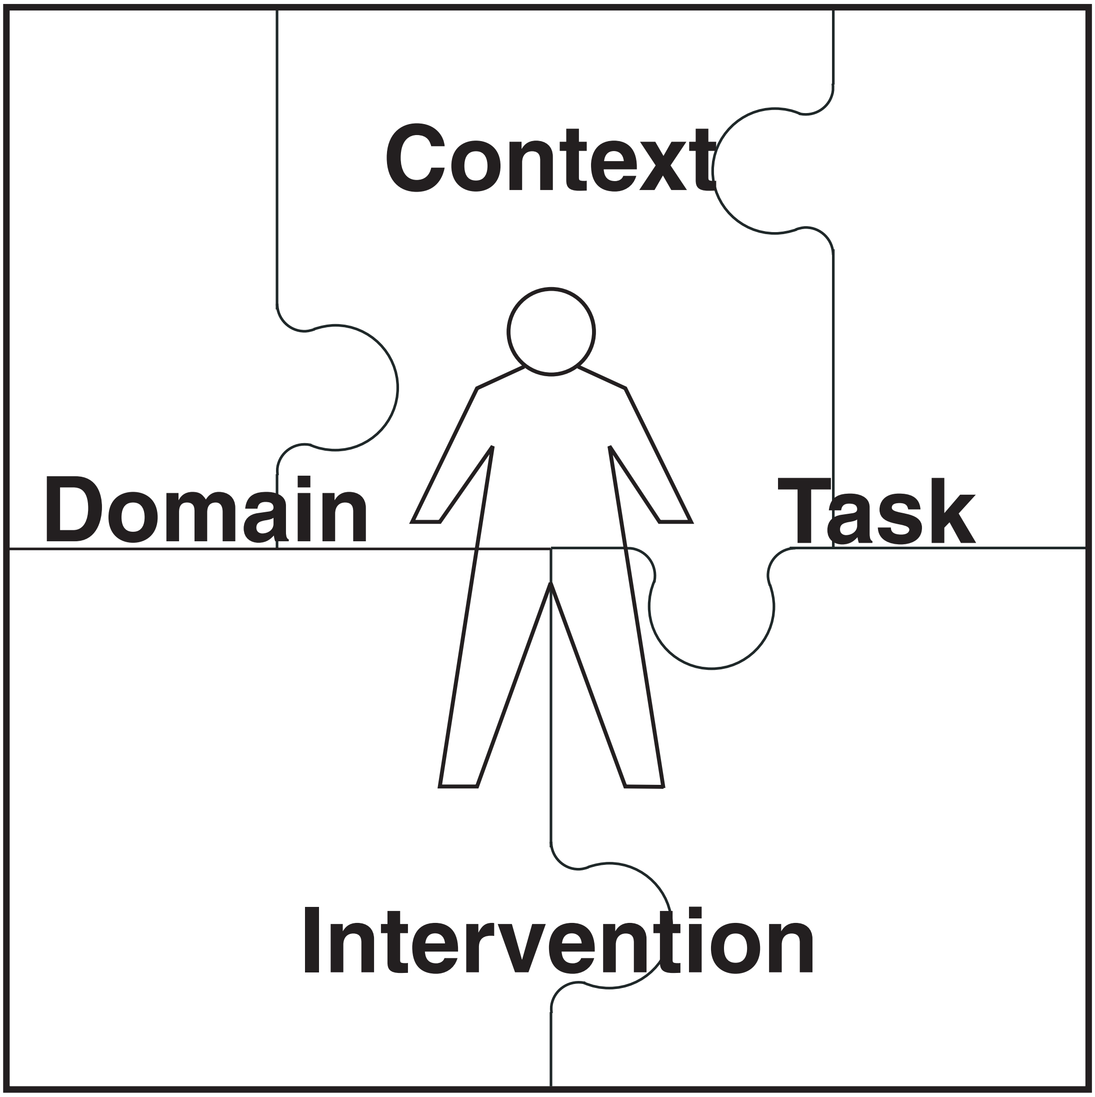
The strategy the practitioner uses to accomplish an effective assessment must, of necessity, be based upon well-grounded, empirically validated theories of cognition and behavior. Only through the use of a theoretical framework are specific predictions regarding performance under a given set of ecological circumstances made possible (Dean, 1985a, 1986; Rothlisberg, 1992). Unfortunately, no single, diagnostic paradigm or theory has proven sufficient to explain fully the vagaries of behavior (D'Amato & Rothlisberg, 1992). Psychoanalytically, behaviorally, and biologically based approaches, as well as other theoretical positions, have been continually challenged not only to describe behavior, but also to provide effective interventions for the populations whom they serve (D'Amato & Dean, 1989b; Gutkin & Reynolds, 1990). Prepackaged programs dealing with psycholinguistic or visual-motor training, and sensory integration training have attempted this, but typically failed to meet the demands of this challenge. Gradually, the field has acknowledged that the effective use of assessment procedures, including educational and psychological tests, is reliant upon a theoretical foundation, which allows the incorporation of information from multiple data sources and environments in such a manner as to increase the amount of effective and appropriate interventions generated.

A framework that is particularly useful is one reliant on an ecological approach. From this perspective, it is critical to evaluate several different aspects of clients' lives in order to develop a better understanding of their functioning within a variety of contexts. The purpose of this chapter is to examine the particular areas of attention and memory, learning processes (input and output), and the special aptitudes of sensory perception, sensory-motor integration, and language/communication to facilitate making informed assessment decisions. One must possess knowledge of the cognitive processes that these tests purport to measure to make judgments about the usefulness of any given instrument with the client's presenting issue. Furthermore, the clinician is provided with an introduction to the types of instruments used to measure memory, learning, and special aptitudes as well as a brief description of those instruments that have strong empirical support for use with children and adult populations. Any one of these areas, on its own, represents a very narrow picture of the overall functioning of an individual. However, when used in conjunction with a more thorough assessment, these areas can provide the missing pieces to the puzzle.

Client difficulties may be attributed not only to intra-individual characteristics, but also to the *domain* of functioning (e.g., social, vocational, educational); the *context* or environment in which the client is expected to function (e.g., job site, classroom, independent living); the requirements of particular assignments, jobs, or responsibilities, *task*; and the strategy used to teach or remediate a difficulty, *intervention* (Geil & D'Amato, 1996). Although the focus of this chapter is memory, learning, and special aptitudes, it may be helpful for the clinician to view these processes as key components within the conceptual framework presented in Figure 1. These areas represent extremely important aspects of psychological functioning and can help to complete the diagnostic picture of an individual by providing critical information to assist the clinician in accurate diagnosis and intervention planning.

4.09.1.1 Assessment Approaches

Before addressing the particular areas of concern, a brief discussion of the assessment process is warranted. Both quantitative and qualitative assessment procedures help to provide a breadth of information concerning individual functioning. A quantitative or product-oriented approach uses standard performance data to assess individuals within and across all the functional domains to be measured by comparing the findings to a normative group (D'Amato, Rothlisberg, & Rhodes, 1997; Dean, 1985a, 1985b; Lezak, 1995). This process detects whether the client's skills show a discrepancy when they are compared to other individuals performing within a normal range. Patterns of performance can also be carefully analyzed to determine the individual client's strengths and weaknesses. Data is usually considered in several ways: level of performance or current functioning (compared to normative standards); pattern of performance (uniqueness of strengths and weaknesses); right–left differences (comparing tests that evaluate both hemispheres including both sides of the body); pathognomic signs (indications of abnormal signs or brain damage); qualitative analysis (behavioral observations of problem solving); intervention



- Domain (social, vocational, educational)
- Context (job site, classroom, independent living)
- Task (assignment, job, responsibility)
- Intervention (remediation, counseling, training)

Figure 1 Conceptual framework of client functioning.

planning (recommendations for appropriate rehabilitation) (Hynd & Semrud-Clikeman, 1990; Jarvis & Barth, 1994; Reitan & Wolfson, 1985, 1993; Sattler, 1992; Selz, 1981).

Most proponents of a quantitative approach recommend a standard or fixed battery of tests. A fixed battery, such as a typical psychoeducational battery (i.e., Wechsler Adult Intelligence Scale-Revised [WAIS-R] or Wechsler Intelligence Scale for Children-3rd Edition [WISC-III], Minnesota Multiphasic Personality Inventory-2nd Edition, Bender Visual-Motor Gestalt Test, Woodcock–Johnson Psychoeducational Battery-Revised) or neuropsychological battery (e.g., *Halstead–Reitan Neuropsychological Test Battery*; Reitan & Wolfson, 1993) involve the same set of instruments for each individual tested (Hynd & Semrud-Clikeman, 1990; Hynd & Willis, 1988). A standard battery format insures that a broad array of appropriate tools is used to cover all significant domains and therefore provide documented results that may be interpreted with ease. In fact, a standard battery approach may be the best choice when and if potential litigation is an issue because this method offers a normative data base to which client profiles can be compared and contrasted (Guilmette & Giuliano, 1991; Reitan & Wolfson, 1995). Despite the apparent strengths of a standardized approach, it has been argued that when developing treatment options, the use of qualitative methods that explore the process of learning or behavior may be better suited than a purely quantitative or product-oriented approach (D'Amato, Rothlisberg, & Leu, in press). For example, if verbal instruction with verbal response is a strength for the client, a preference for left hemisphere processing might be entertained and interventions utilizing a verbal component could be tailored with that hypothesis in mind. Likewise, if a client demonstrated a strength in simultaneous processing of information, a global concept or visual chart could be introduced before presenting the individual skills necessary to accomplish the particular task.

A second strategy, the qualitative approach or process-oriented approach, uses informal procedures such as direct observation of particular skills to analyze the specific patterns and processes in order to understand better the intricacies of the client's psychological processes (Lezak, 1995). Practitioners utilize a client's individual pattern of responses or results to guide the assessment process. That is, if a client was observed to have difficulty with memory tasks, that particular area would be investigated in more detail through the use of additional measures of memory. A decision-making process (i.e., whether to explore an area further or move on to another area of functioning) occurs after each item and is based on clinical judgment. By employing this strategy, it is argued that a clinician is better able to understand the complexities of an individual's performance and focus on the impaired functional system (D'Amato, Rothlisberg, & Leu, in press; Golden, 1981; Luria, 1980). Unique and individualized sets of procedures, questions, or tasks shape the evaluation process and might include an individual case study approach consisting of a mental status exam, observation, and symptom checklists. From an educational perspective, a psychologist using a qualitative approach might gather information using work samples, classroom observations, or dynamic assessment strategies (e.g., Campione & Brown, 1987; Feuerstein, Rand, & Hoffman, 1979). While the major areas traditionally covered in a qualitative evaluation seem comprehensive (e.g., investigations of motor functions, expressive speech, writing, reading; see Hynd & Semrud-Clikeman, 1990), this view does not rely on standardized batteries or clear comparisons to normative populations. Instead, the selection of strategies utilized follows significant clinical patient–practitioner interactions. Although the flexibility and individualization apparent in this method is appealing, it requires a great deal of clinical experience to make accurate interpretations of behaviors, and problems with reliability and validity are ever-present (Lezak, 1995).

A third approach, and one which is likely used by the majority of clinicians, is the use of integrated data. Indeed, any time examiners note an examinee's reaction to a task, the response time involved, or any problem-solving strategies employed (e.g., rehearsal, verbal cuing), they are inferring the underlying processes being used (D'Amato, Rothlisberg, & Leu, in press; Taylor, 1988; Taylor & Fletcher, 1990). Because all individuals show a distinctive pattern of learning and behavioral characteristics, it is improbable that any given test, or even battery of tests, in isolation, can capture the range of skills exhibited by that individual. Furthermore, test scores that are interpreted without consideration to the context of the examination may be objective but are meaningless in their individual application (Lezak, 1995). Likewise, clinical observations unsupported by standardized and quantifiable testing may provide a rich picture of the client's current functioning but lack the comparability necessary for many diagnostic and planning decisions. Thus it is expected that most practitioners are integrated in their assessment practices, relying on both norm-referenced comparisons and qualitative procedures and observations to enrich their views of their clients. In fact, Lezak (1995) suggests that either method is incomplete without the other.

4.09.1.2 Evaluation of Domain Areas

Regardless of the position of the examiner along the quantitative–qualitative continuum, it is helpful to conceptualize an evaluation of domain areas, rather than simply focusing on tests or specific problem behaviors. The following domains are offered because of their importance to daily functioning and usefulness to intervention development in educational and vocational settings (Begali, 1994; D'Amato & Rothlisberg, 1992; D'Amato, Rothlisberg, & Leu, in press; Gaddes & Edgell, 1994). These domains include:

(i) intelligence/cognitive abilities,
(ii) personality/behavior/family information,
(iii) memory and attention,
(iv) learning processes,
(v) academic achievement,
(vi) sensory/perceptual systems,
(vii) motor functions, and
(viii) communication/language skills.

The areas of intelligence and personality assessment are covered in more depth in Chapters 8 and 12 of this volume. The remaining areas are divided into the subareas presented in Table 1 to provide a better understanding of the types of skills encompassed in each of these domains. Given the complexity of these areas, all should be considered both formally and informally. Direct observations and interviews with the client and family members are vital components in evaluating any individual's performance. The selection of tests utilized to evaluate these abilities will vary greatly depending on the unique needs of the individual, considered in tandem with the reason for referral.

Data on the functioning of these domains provides useful information for the clinical psychologist. As demonstrated in Table 2, a variety of testing instruments are appropriate in each of these areas. It should be noted that different authors have suggested various subsets of domains for analysis as well as recommending literally hundreds of other measures as appropriate for children and adults (Batchelor, 1996a; Begali, 1992; Dean & Gray, 1990; Gaddes & Edgell, 1994; Hynd & Willis, 1988; Lezak, 1995). Thus the instruments categorized in Table 2 represent only a sampling of available measures. The practitioner must take responsibility for carefully matching the individual with potential assessment options, after considering the distinct features of the instruments and the unique needs of the client.

Table 1 Subdomains of attention and memory, learning process, and special aptitudes.

Attention and memory
Attention
Concentration or vigilance
Visual memory
Verbal memory
Recall
Recognition
Short-term memory
Long-term memory
Learning processes (input and output)
Visual processing
Motoric processing
Auditory processing
Linguistic/verbal processing
Simultaneous processing
Sequential processing
Academic achievement
Sensory/perceptual
Visual
Auditory
Tactile-kinesthetic
Integrated
Motor functions
Strength
Speed
Coordination
Lateral preference
Sensory-motor integration
Communication/language skills
Receptive vocabulary
Expressive vocabulary
Speech/language
Written language

4.09.1.3 Intervention Approaches

The referral question for any client is rarely "how is this individual functioning today?"; instead the referral source is most often interested in the extent of decline following an injury or illness, the expected future performance in school or work settings, or how to maximize a client's potential given certain difficulties (e.g., head injury, learning disability; Long, 1996). Several decisions must be made in relation to the intervention strategy and will be reliant on the quality of the information provided by the assessment. Intervention may be conceptualized using one of three approaches: remediation (retraining a previously learned skill), compensation (learning to use other strengths to offset a lost skill), or a combination of both (D'Amato & Rothlisberg, 1996). In particular, it is critical to determine the level of intervention on which to focus one's efforts and the ideal combination of strategies that will work best with an individual. Rehabilitative efforts emphasize enabling clients to reach their goals in educational, vocational, social, and recreational settings despite difficulties related to their deficits. To reach this end, intervention strategies may focus on:

(i) remediating or retraining impaired cognitive processes (if there is a reason to believe that the process can be improved with practice),

(ii) helping the client to develop new skills to compensate for residual deficits,

(iii) creating classroom or workplace adaptations and other environmental compensations that permit effective performance despite residual deficits,

(iv) choosing instructional or therapeutic procedures that best fit the client's profile of strengths and weaknesses, and

(v) promoting improved metacognitive awareness of strengths and needs so that the client can become an active participant in selecting goals and interventions strategies (Ylvisaker, Szekeres, & Hartwick, 1994).

Table 2 Common instruments and procedures used to evaluate attention and memory, learning processes and special aptitudes.

Attention and memory

Test of Variables of Attention (TOVA™)
Visual Search and Attention Test
Tests of Memory and Learning
Wechsler Memory Scale-Revised
Wide range assessment of memory and learning

Learning processes: input and integration

Detroit Tests of Learning Aptitude-3
Swanson's Cognitive Processing Test
Children's Auditory Verbal Learning Test
Tactile Performance Test (Halstead–Reitan Battery)
Speech–Sounds Perception Test (Halstead–Reitan Battery)
Wisconsin Card Sort

Academic achievement: output

Woodcock–Johnson Psycho-educational Battery-Revised: Achievement
Peabody Individual Achievement Test-Revised
Wechsler Individual Achievement Test
Kaufman Test of Educational Achievement
Keymath-revised
Woodcock Reading Mastery Test-Revised
Test of Reading Comprehension-3
Test of Written Language-3

4.09.2 ASSESSMENT OF MEMORY

Memory is one of the most important cognitive functions to be assessed. It is a highly complex cognitive function that encompasses several relatively discrete stages: reception and registration of sensory stimuli, temporary short-term storage of information, storage of the information in a more permanent form (long-term memory), and recall and retrieval of previously stored information (Shiffrin & Atkinson, 1969; Taylor, Fletcher, & Satz, 1984). Functioning at each stage depends upon the integrity of the previous steps, with any interruption in the hierarchy having the potential to interfere with memory storage or retrieval. For example, difficulties with attention, which most closely relates to the first stage of memory, would obviously lead to problems in short- and long-term storage as well as later retrieval of the information. A further source of complexity in understanding and measuring this skill is the variety of theoretical approaches from which memory can be conceptualized, including information processing, neuropsychological, and behavioral perspectives.

Memory testing is very useful for assessing the possibility of organic disease, in helping to differentiate between organic and psychiatric disorders, and in determining the functional significance of a memory problem (Black & Strub, 1994). Most of the major neurobehavioral disorders such as dementia, confusional states, amnesia, material-specific memory/learning defects, and attentional dysfunction are those in which disturbances of memory and attention are the prominent clinical features (Hamsher, 1984). However, individuals with depression, post-traumatic stress disorder, dissociative disorders (e.g., dissociative amnesia, dissociative identity disorders) might also demonstrate attention and memory deficits (American Psychiatric Association, 1994). Memory skills represent a difficult area to address because of the variety of levels (e.g., working, short-term, long-term) and the potential implications of a deficit. So too, memory to some degree is modality specific; that is, for example, some individuals may have impaired verbal memory but intact visual memory. Thus, it is important to look at various components of memory rather than obtaining a simple global memory score. Tests that provide a single memory score offer a myopic and problematic view of the multifaceted quality of memory.

4.09.2.1 Attention

One of the key components to memory and learning is the ability to attend selectively to relevant information that we are presented with during the course of daily functioning. Attention is an extremely important basic function which refers to the client's ability to maintain awareness and to focus on a specified environmental stimulus, while screening out other stimuli that are potentially distracting (Black & Strub, 1994). Being able to attend has three major benefits for an individual: accuracy, speed, and maintenance of mental processing (LaBerge, 1995). Attention deficits appear as distractibility or impaired ability for focused behavior, regardless of the individual's intention (Lezak, 1995). Intact attention is a necessary condition of concentration which requires an individual to sustain attention over an extended period of time. Concentration problems may be due to a simple attentional disturbance, or to inability to maintain a purposeful attentional focus or, as is often the case, to both problems. This skill is important for adequate performance on any cognitive task, and can be impaired as a result of either an organic or emotional disorder (D'Amato, 1990; Dean, 1985a). Several psychological difficulties have been associated with attentional problems such as impulsivity, distractibility, and poor social judgment. Tests that require mental effort and persistence can measure an individual's ability to select, sustain, and shift attention (Slomka & Tarter, 1993). By comparing performance on various types of tasks, the practitioner is able to distinguish a global attention deficit from the more discrete, task-specific problems of concentration and tracking.

It is important to clarify the nature of an attention problem by observing people's general behavior as well as their performance on tests involving concentration. An interview with family members can provide important information about attentiveness and susceptibility to distraction. So too, formal or quantitative measures of attention and short-term memory can be derived from the Digit Span and Coding or Digit Symbol subtests of the WISC-III or WAIS-R tests. Some of the more specific, informal measures of attention and concentration might include observation, a digit span task, and a vigilance task as outlined by Strub and Black (1993). The individual is given orally a series of random letters with the letter "A" occurring with greater frequency than the other letters. The individual is instructed to signal whenever the targeted letter (i.e., A) is heard. The individual's performance is scored for errors, which are rarely made by those without attention or vigilance difficulties (Black & Strub, 1994). More formal measures such as the *Visual Search and Attention Test* (Trenerry, Crosson, DeBoe, & Leber, 1990) can be used for adults. This test purports to measure sustained attention and visual scanning. The test consists of four 60-second trials and is made up of four tasks which become increasingly complex. The respondent is required to cross out letters or symbols that match a target. Normative tables are provided and arranged in four 10-year age bands, an 18–19 year age band, and a 60+ age band, and the statistical properties appear to be adequate (Hooper, 1995). Based on how the stimuli are presented, these tasks can provide a measure of either visual or auditory vigilance.

Vigilance tests are often referred to as continuous performance tests (CPTs), which are automated tasks, now computer-administered, that purport to measure sustained attention (Greenberg & Waldman, 1993; Lassiter, D'Amato, Raggio, Whitten, & Bardos, 1994; Rosvold, Mirsky, Sarason, Bransome, & Beck, 1956). CPTs have become a popular tool for clinicians to measure attentional performance, response inhibition, and medication monitoring in both children and adults (Eliason & Richman, 1987; Lassiter et al., 1994). Many versions of CPT have been developed since the original but the basic methodology of these tasks remains fairly constant. Clients are presented with a variety of stimuli that are displayed for a short period of time, and are instructed to respond to a predefined "target" stimulus. A number of different indices can be recorded with these tasks including omissions errors (i.e., failing to detect target stimulus), commissions (i.e., responding to nontarget stimulus), and response times for correct detections (Greenberg & Waldman, 1993). Commission errors are considered to be indicative of impulsivity and omission errors are thought to denote inattention (Eliason & Richman, 1987; Lassiter et al., 1994). Examples of these types of tests include the CPT-2 (Lindgren & Lyon, 1983), the *Raggio Evaluation of Attention Deficit Disorder* (Raggio, 1991), and the *Test of Variables of Attention* (*TOVA*$^{\mathrm{TM}}$; Greenberg, 1993).

The *TOVA*$^{\mathrm{TM}}$ is a nonlanguage-based, visual continuous performance test. This test runs for 23 minutes on a fixed-interval schedule and presents two easily discriminated visual stimuli for 100 milliseconds every two seconds. It was designed for use in the diagnosis and monitoring of pharmacotherapy of children and adults with attention deficit disorders and can be used with individuals age five to adulthood. The test does not require right-left discrimination and has negligible practice effects. Recently, the authors of the *TOVA*$^{\mathrm{TM}}$ have created developmental norms for children aged 6 to 16 which are available for few other CPT versions (Greenberg & Waldman, 1993). This type of tool may also be useful in assisting the clinician in the differential diagnosis of children and adolescents experiencing externalizing problems (e.g., attention deficit disorder, oppositional defiant disorder, conduct disorder, and aggression) and/or learning disabilities (Eliason & Richman, 1987; Greenberg & Waldman, 1993).

Despite the technological advances and newly defined norms, CPTs present a quandary to practitioners because of the variety of attributes that the tests reportedly measure. Some see these tests as measuring attention and impulsivity (Klee & Garfinkel, 1983), educational achievement (Campbell, D'Amato, Raggio, & Stephens, 1991), behavior (Lassiter et al. 1994), general neuropsychological functioning (Halperin, Sharma, Greenblatt, & Schwartz, 1991), and information processing (Swanson, 1981). Given this variance, a practitioner is left with the question of how to interpret the test results of a particular client. While research supports many of these claims, different versions of the CPTs have been used in these studies, with different samples of children and adults. So too, the validity of CPTs have been related to material collected from teachers, parents, and peers, and from standardized intelligence, achievement, and personality tests. While it is obvious that CPTs measure issues critical to learning and memory, the specificity of these instruments remains unclear. In conclusion, Morris (1996) noted that many of the measures that purported specifically to measure sustained attention often measured other variables, and thus many of these tests have poor construct validation and may be more appropriately viewed as multidimensional in nature. As an alternative, Barkley (1996) advocates the use of more natural tasks to study attention in an individual. He concludes that CPT-type tasks are unrelated to our daily functioning and thus, an individual's performance on such tasks is irrelevant. In response to this concern, several investigators have reportedly used television viewing, performance on classroom tasks, video games, and driving performance as a means of studying attention and its deficits in various groups of children and young adults (Barkley, 1996).

4.09.2.2 Short-term and Long-term Memory

As already noted, each component of the memory process is reliant upon the previous steps. If information in sensory storage undergoes additional processing, it becomes a more lasting memory (short-term or long-term). Furthermore, these different memory functions must be systematically reviewed through visual and aural modalities using both recall and recognition tasks. Lezak (1995) suggests that at a minimum, the memory examination should include: *immediate retention* tasks, including short-term memory with interference; *learning* in terms of extent of recent memory, learning capacity, and how well newly learned material is retained; and efficiency of *retrieval* of both recently learned and long-stored information (i.e., remote memory).

Informal methods of assessment include tests of immediate recall such as digit repetition and/or sentence repetition, interviewing for information from remote memory (e.g., "where were you born?"), and new learning ability (e.g., immediate recall for a verbal story, asking the individual to remember four unrelated words for a span of 5, 10, and 30 minutes). During this last task, the examiner can provide recognition cues if the individual is having difficulty remembering the words. It is expected that those without difficulties will remember all words, while those with brain damage might be expected to remember one (Black & Strub, 1994). For aphasic clients or those with other speech or language problems, an informal measure of visual memory can be completed by hiding five objects around the interview room as the client names each item as it is hidden. After 10 minutes, the client is asked for name and location of each item. Reportedly, both normal and lower IQ clients should be able to find all five objects, with slightly lower performance for older patients (approximately four objects) (Black & Strub, 1994; Simpson, Black, & Strub, 1986). These memory tasks should be supplemented with observations and interviews with family members. So too, if an ability measure such as the WISC-III or WAIS-R is administered, performance on Digit Span can provide information on immediate verbal retention and the information subtest can be an indicator of the extent of remote memory in an individual.

To complete an assessment of the major dimensions of memory, Lezak (1995) has suggested including:

(i) a test of configural recall and attention such as the visual reproduction subtest on the *Wechsler Memory Scale* (Wechsler, 1987) or the *Benton Visual Retention Test* (Benton-Sivan, 1992);

(ii) a paragraph for recall to examine learning and retention of meaningful verbal material; and

(iii) a test of learning ability that gives a learning curve and includes a recognition trial, such as Rey's Auditory-Verbal Learning Test (for review see Lezak, 1995).

These techniques should be integrated into the general clinical interview to create a varied testing format, to enable the practitioner to use nonmemory tasks as interference activities, and to reduce stress in those clients who have memory impairments and are concerned about their abilities (Black & Strub, 1994).

There are numerous formal instruments available which measure different dimensions of memory. For children and adolescents, the *Wide Range Assessment of Memory and Learning* (Sheslow & Adams, 1990), and the *Test of Memory and Learning* (*TOMAL*; Reynolds & Bigler, 1994) can be used to evaluate individual strengths and weaknesses in the areas of memory and attention. In particular, the *TOMAL* represents a reliable, empirically sound measure for children and adolescents. The *TOMAL* consists of four core indexes comprising Verbal Memory, Nonverbal Memory, Composite Memory, and Delayed Recall. Supplementary indexes for Learning, Attention and Concentration, Sequential Memory, Free Recall, and Associative Recall are also provided. Subtests include Memory for Stories, Facial Memory, Word Selective Reminding, Visual Selective Reminding, Object Recall, Abstract Visual Memory, Digits Forward, Visual Sequential Memory, Paired Recall, Memory-for-Location, Manual Imitation, Letters Forward, Digits Backward, and Letters Backward. The *TOMAL* was standardized for children aged 5 to 19.

The *TOMAL* boasts many unique features, including a great variety of memory indexes (Reynolds & Bigler, 1994). While some of the subtests appear similar to other memory measures, some unique features of this test include a learning index where teaching is permissible, a sequential memory index, and an attention and concentration index. Delayed recall subtests are also available and are offered as an evaluation of forgetting or memory decay. It is possible to compare the examinee's own personal learning curve with a standardized learning curve. The test is easy to administer and generally user-friendly. Its psychometric properties appear to be well-developed. In the *TOMAL* subtests, 63% of the reliability coefficients are at or exceed 0.9, 31% are between 0.8 and 0.89, and only 6% fall below 0.8. Test–retest coefficients range from 0.71 to 0.91. Support for the validity of this instrument was determined through indices of content validity, construct validity (e.g., factor analytic studies), and criterion-related validity.

Assessment of memory dysfunction in adults is easier than in children because their period of rapid intellectual, academic, and physical (including neurological) development has ended (Reynolds & Bigler, 1994). In adults, memory dysfunction is associated with a variety of well-defined disorders, and in many individuals is one of the earliest and key symptoms such as in Korsakoff's disease and various other dementias including Alzheimer's disease. Because of the key role of evaluating memory in the clinical setting, there are a number of instruments designed for memory assessment in older populations including the *Doors and People: A Test of Visual and Verbal Recall and Recognition* (Baddeley, Emslie, & Nimmo-Smith, 1994), the *Memory Assessment Scales* (*MAS*; Williams, 1991), and the *Wechsler Memory Scale-Revised* (*WMS-R*; Wechsler, 1987).

The *WMS-R* (Wechsler, 1987) provides an extensive measure of several dimensions of memory. It consists of eight short-term memory tests, four delayed-recall subtests, and a brief screening measure of mental status (i.e., information and orientation questions). The eight short-term memory tests yield four composite scores: Verbal Memory, Visual Memory, Total General Memory, and Attention/Concentration. The delayed-recall measures can be combined to derive a fifth composite score, Delayed Recall. The test is intended for use for individuals ranging in age from 16 to 74 and requires approximately 50 minutes to administer. The psychometric properties of the *WMS-R* are questionable in terms of low reliability coefficients for the composite scores (average $r = 0.74$), but provides stronger support for the General Memory and Attention/Concentration (average $r = 0.81$) scores. Although the *WMS-R* demonstrated satisfactory discrimination power between various clinical groups, factor analyses supported a two-factor rather than the hypothesized five-factor model. Huebner (1992) concluded that this instrument must be used cautiously in making clinical decisions about individuals and interpretation should be restricted to General Memory and Attention/Concentration ability.

For adolescents and adults, the *MAS* (Williams, 1991) also provides a valid, reliable, and comprehensive measure of memory functioning. The *MAS* was standardized for use with adults aged 18 to 90. The major functions measured by the *MAS* include: verbal and nonverbal learning and immediate memory; verbal and nonverbal attention, concentration, and short-term memory; and memory for verbal and nonverbal material following delay. In addition, measures of recognition, intrusions during verbal learning recall, and retrieval strategies are also available. The test consists of 12 subtests based on seven memory tasks.

Five of the subtests assess the retention of information learned in a subtest administered earlier in the sequence. Total testing time is approximately one hour. Test-retest reliability for the *MAS* was estimated using generalizability coefficients and these correlations averaged 0.85 for the subtests, 0.9 for the summary scales (i.e., Short-Term Memory, Verbal Memory, and Visual Memory), and 0.95 for the global memory scale. The validity of the *MAS* was established using three types of studies: convergent and discriminant validity, factorial validity, and group differentiation. Despite these strengths, Berk (1995) concluded that clinicians should use caution in interpreting the scores until some technical problems (e.g., inadequate samples, lack of evidence for content validity) can be corrected.

4.09.2.3 Memory: Implications for Intervention

Because memory is multifaceted, interventions in the memory domain must also be multidimensional. Interventions may be divided several ways; those involving language, those that are nonverbal, those requiring long, short, or intermediate memory, and those that use a combined approach to aid in retention (Gaddes & Edgell, 1994; Lezak, 1995). Strategy selection depends on accessing the strengths of the clients or, in the case of injury or disease, accessing those parts of the brain which have been least impacted. For example, learners who have difficulty with nonverbal memory tasks but have retained verbal skills may benefit from memory interventions that use language. Mnemonic devices may be used to assist in recall of information if a series of problem-solving steps is required (Mastropieri & Scruggs, 1989). For those with more difficulty remembering, some simple techniques such as writing all meetings in an appointment book or using grocery shopping lists and daily "to do" lists are practical.

4.09.3 ASSESSMENT OF LEARNING

Memory is a ubiquitous component of daily life and is fundamental to the process of learning. One must be able to remember in order to demonstrate learning. The classic definition of learning describes it as changes in behavior as a result of experience. Some have even considered this definition of learning as also defining memory (e.g., see Kolb & Whishaw, 1990). Despite this relatively simple definition, the learning process itself defies easy explanation. Learning can be approached from a neuropsychological (e.g., planning, attention, simultaneous, successive [PASS] model; Das, Naglieri, & Kirby, 1994), behavioral (e.g., classical and operant conditioning; Baldwin & Baldwin, 1986), cognitive (e.g., information processing; Pressley & Levin, 1983), or social (e.g., social learning and modeling; Bandura, 1977) perspectives, to name but a few. Furthermore, the distinction drawn between measures of memory and measures of learning is tenuous at best since all instruments that evaluate an individual's learning process will automatically include aspects of memory functioning. Because learning takes center stage as one of our functions of daily living, it represents a critical area to evaluate. By fully evaluating several components of learning, clinicians can determine where the process is breaking down and provide recommendations for rehabilitation. An understanding of how a client best learns also has important implications for the types of therapeutic strategies that will most likely be successful. For example, if an adolescent has difficulty processing and remembering auditory information, talk therapy may not be the best approach. Supplementing discussion with role play, videos, and other visual cues may be necessary to facilitate the client's acquisition of new knowledge.

Difficulties in learning can be attributed to a number of disorders, including the general category of learning disorders (e.g., dyslexia, dyscalculia), traumatic brain injuries, drug and alcohol abuse, and medical disorders (e.g., strokes, Alzheimer's disease). Indeed, all of the variables that can affect attention and memory will also impact learning. Furthermore, certain chronic medical conditions can play a role in learning difficulties. For example, childhood diabetes is associated with subtle problems with respect to visuospatial and visuomotor processing (e.g., Rovet, Ehrlich, & Hoppe, 1988), verbal abilities (Kovacs, Goldston, & Ivengar, 1992), and memory and attention problems, which translate into increased risk for difficulties in academic achievement, (Kovacs et al., 1992; Rovet, Ehrlich, Czuchta & Akler, 1993). So too, sickle cell anemia, an inherited disorder in people of African descent, often produces some subtle cognitive impairments that can affect school achievement negatively (Brown, Armstrong, & Eckman, 1993). Among individuals with traumatic brain injuries, learning process problems may be reflected as an uncertainty as to whether a concept has been learned or not (Cohen, 1991).

4.09.3.1 Models of Learning

Information-processing theories have proved extremely useful in conceptualizing learning because this model can be applied to any given cognitive task and allows the practitioner to specify where the learning process is breaking down. Silver (1993) proposed an information-processing model based on four steps: input (how information from the sense organs enters the brain), integration (interpreting and processing the information), storage (storing the information for later retrieval), and output (expressing information via language or muscle activity). Learning is reliant upon each of the first three steps and is observed or inferred from the fourth step. Other models of information processing highlight the importance of the working memory in skill acquisition and learning (Baddeley, 1986; Just & Carpenter, 1992; Swanson, 1995). Working memory has traditionally been defined as a system of limited capacity for the temporary maintenance and manipulation of information (e.g., Baddeley, 1986; Just & Carpenter, 1992) and most closely corresponds to the integration step in Silver's model. Tasks that measure working memory are those that require the client to remember a small amount of material for a short time while simultaneously carrying out further operations. In daily life, these tasks might include remembering a person's address while listening to instructions about how to reach a specific destination (Swanson, 1995). When viewed from this perspective, working memory differs from the related concept of short-term memory which is typically described as remembering small amounts of material and reproducing it without integrating or transforming the information in any way (e.g., repeating back a series of numbers) (Cantor, Engle, & Hamilton, 1991; Just & Carpenter, 1992). Working memory appears to be extremely important to an individual's ability to learn, and in adult samples has correlations of 0.55–0.92 with reading and intelligence measures (e.g., Daneman & Carpenter, 1980; Kyllonen & Christal, 1990).

In an effort to promote the notion that input and integration of stimuli can impact subsequent learning, Cronbach and Snow (1977) have advanced a theory suggesting that some types of individuals might benefit from one form of treatment, whereas others might benefit from another type of treatment: an aptitude by treatment interaction (ATI). Many researchers and educators alike believe that matching learner characteristics with treatment approaches can enhance learning (e.g., Cronbach & Snow, 1977; Resnick, 1976; Reynolds, 1981b). However, subsequent studies have demonstrated little support for this theory (e.g., Arter & Jenkins, 1977; Tarver & Dawson, 1978). Initially, theories of input examined learner modalities (e.g., visual, auditory, kinesthetic), which were later deemed to be too simplistic (Arter & Jenkins, 1977; Kaufman, 1994; Tarver & Dawson, 1978). More recently, neuropsychological models have been applied to ATIs and offer promise for identifying aptitudes and prescribing treatments (D'Amato, 1990; Hartlage & Telzrow, 1983). One of the major techniques that Cronbach and Snow (1977) suggested for matching treatment approaches with learner aptitudes was "capitalization of strengths." Our increasing knowledge of how the brain functions allows clinicians to obtain a more detailed understanding of how a client learns new information. For example, although the cerebral hemispheres act in concert, the right hemisphere seems to be specialized for holistic, spatial, and/or nonverbal reasoning whereas the left shows a preference for verbal, serial, and/or analytic type tasks (Gaddes & Edgell, 1994; Lezak, 1995; Reynolds, 1981a; Walsh, 1978). Similarly, models of cognitive processing have been proposed that agree with the specialization of how scientists think the brain processes information; some have called this preferential processing styles (D'Amato, 1990). For example, simultaneous processing ability has been affiliated with the right hemisphere because of its holistic nature; it deals with the synthesis of parts into wholes and is often implicitly spatial (Das, Kirby, & Jarman, 1979). In contrast, the left hemisphere processes information using a more successive/sequential method, considering serial or temporal order of input (Dean, 1984, 1986). Models of brain organization have also been proposed that attempt to explain the diversity and complexity of behavior.

An expansion of the hemispheric specialization approach is offered in the planning, attention, simultaneous, successive (PASS) cognitive processing model (Das et al., 1994) which proposes four processing components. This model is based on the neuropsychological model of Luria (1970, 1973, 1980; Reynolds, 1981a) and presents a comprehensive theoretical model by which cognitive processes can be examined. On the basis of his clinical investigations with brain-injured patients, Luria (1973) suggested that there are three functional units that provide three classes of cognitive processes (i.e., memory, conceptual, and perceptual) responsible for all mental activity. Figure 2 provides a graphic presentation of the PASS model of cognitive processing. The functional units work in concert to produce behavior and provide arousal and attentional (first unit), simultaneous-successive (second unit), and planning (third unit) cognitive processes. The PASS model separates the second unit into two individual processes (i.e., simultaneous and sequential). Instruments can be used to measure individual strengths in these different styles of processing.

Figure 2 PASS model of cognitive processing. (*Assessment of Cognitive Processes: The Pass Theory of Intelligence* (p. 21), by J. P. Das, J. A. Naglieri, and J. R. Kirby, 1994, New York: Allyn & Bacon. Copyright 1994, by Allyn & Bacon. Reprinted with permission.)

Knowledge of the brain and theories governing information processing can determine the types of data collected during the assessment phase. For example, instead of simply observing whether the individual was successful at a task or set of measures, the practitioner looks beyond the product to determine the influence of related factors. These factors can include the nature of the stimuli used (visual, verbal, tactile), the method of presentation (visual, verbal, concrete, social), the type of response desired (verbal, motor, constructional), and the response time allowed (timed, untimed; Cooley & Morris, 1990). Other researchers have advocated a move to an even more intense examination of processing through the use of dynamic assessment strategies (Campione & Brown, 1987; Feuerstein et al., 1979; Palincsar, Brown, & Campione, 1991). Theoretically, this strategy allows the examiner to obtain information about the client's responsiveness to hints or probes, and thus elicits processing potential (Swanson, 1995). When an examinee is having difficulty, the examiner attempts to move the individual from failure to success by modifying the format, providing more trials, providing information on successful strategies, or offering increasingly more direct cues, hints, or prompts (Swanson, 1995). This approach allows the examiner an opportunity to evaluate performance change in the examinee with and without assistance. However, there is little if any standardized information available on this technique and it has been criticized for its clinical nature and poor reliability (e.g., Palincsar et al., 1991).

4.09.3.2 Learning Processes: Input and Integration

Generally, three approaches have been utilized when evaluating how individuals preferentially process information. The first approach, seen as the traditional approach, employs established measures (such as the WISC-III) with the practitioner seeking to understand information processing through an analysis of common test results such as reviewing global scores, subtests, and clusters of subtests (Kaufman, 1990, 1994). For example, a pattern of strengths on the Picture Completion, Block Design, Object Assembly and corresponding weaknesses in Picture Arrangement and Coding might suggest meaningful differences in a client's mental processing style (i.e., right hemispheric functioning vs. left hemispheric functioning from cerebral specialization theory, or simultaneous vs. successive coding from Luria theory). The second view of information processing, considered the informal approach, considers observations, checklists, and learning style inventories to understand how individuals learn. From this view, individuals who seem to profit most from visual clues may be seen as visual learners, and might be taught utilizing overheads, visual diagrams, and worksheets. The final approach to understanding processing stems from the administration and analysis of the many unique measures that have been offered as learning style or processing tests. This approach is seen as a nontraditional test approach (D'Amato, Rothlisberg, & Rhodes, 1997). These specialized measures of performance in learning do not fall neatly within the traditional domains of intelligence, achievement, or neuropsychological processing. These tests, including the *Detroit Tests of Learning Aptitude-3* (*DTLA-3*; Hammill, 1991), the *Swanson Cognitive Processing Test* (*S-CPT*; Swanson, 1996), the *Children's Auditory Verbal Learning Test-2* (Talley, 1993), and others can offer valuable information concerning how individuals attend to and deal with new information. While practitioners have used these instruments to document clients' strengths and weaknesses, diagnose problems, and chart the course of disorders, these instruments offer more practical information concerning rehabilitation or program planning than for diagnostic activities.

Neuropsychological tests have also been seen by some to evaluate variables related to learning processes. In fact, the *Halstead Reitan Neuropsychological Test Battery* (Reitan & Wolfson, 1985, 1993) reportedly measures problem solving, tactual discrimination, sensory recognition, spatial memory, verbal-auditory discrimination, attention, nonverbal auditory discrimination, psychomotor speed, and manual dexterity as well as several other skills (D'Amato, 1990; Dean, 1985a, 1985b, 1986; Lezak, 1995). Individuals interested in a neuropsychological approach to processing should consult some of the recommended references and Chapters 10 and 11, this volume.

The area of learning processing is more difficult to evaluate and is often subsumed within the intelligence or achievement domains. One measure that has a long history in the evaluation of processing styles is the *DTLA-3*. This instrument was designed for use with individuals aged 6 to 17. More recently, two other versions of this test, the *Detroit Tests of Learning Aptitude-Adult* (Hammill & Bryant, 1991a) and *Detroit Test of Learning Aptitude-Primary* (2nd ed.; Hammill & Bryant, 1991b) have expanded the usefulness of this instrument to include individuals from age 2 to 79. The *DTLA-3* consists of 11 subtests comprising: Word Opposites, Design Sequences, Sentence Imitations, Reversed Letters, Story Construction, Design Reproduction, Basic Information, Symbolic Relations, Word Sequences, Story Sequences, Picture Fragments; and 16 composite scores: General Mental Ability Composite, Optimal Level Composite, Domain Composites (Verbal, Nonverbal, Attention-Enhanced, Attention-Reduced, Motor-Enhanced, Motor-Reduced), Theoretical Composites (Fluid Intelligence, Crystallized Intelligence, Associative Level, Cognitive Level, Simultaneous Processing, Successive Processing, Verbal Scale, and

Performance Scale). The testing time is estimated to vary from 50 minutes to two hours. The internal consistency reliabilities for the subtests are sufficiently high; however, the data on stability are limited. It was also noted that the factor analysis does not support the construct validity of the different composites. In fact, only four factors (one being a residual or difficult to interpret category) were identified in the manual. Despite these concerns, Poteat (1995) notes that the *DTLA-3* can be recommended as an adjunct to some of the better developed measures of intelligence and it provides some potentially valuable information about diverse abilities. The *DTLA* has been especially helpful when evaluating children who suffer from learning disabilities or traumatic brain injuries. The *Detroit Tests of Learning Aptitude-Adult* (Hammill & Bryant, 1991a) comprises 12 subtests and 16 composites and measures areas similar to the *DTLA-3*. Internal consistency reliability of all scores approximates 0.9 for all ages. This instrument represents a useful tool in practice because of the type of information it can provide regarding client cognitive functioning in relation to learning new information.

A very recent contribution to the field of cognitive processing is the *S-CPT* (Swanson, 1996) which purports to measure different aspects of intellectual functioning and information processing potential. The battery, designed for use with persons age five to adulthood, draws from the work on information processing theory and dynamic assessment. The subtests in this measure are as follows: Rhyming Words, Visual Matrix, Auditory Digit Sequencing, Mapping and Directions, Story Retelling, Picture Sequencing, Phrase Recall, Spatial Organization, Semantic Association, Semantic Categorization, and Nonverbal Sequencing. This standardized test battery can be administered in an abbreviated form (five subtests) or in a complete form under traditional or interactive testing conditions. Normative data for the *S-CPT* were gathered on 1611 children and adults. The author reports high levels of internal reliability and high construct and criterion-related validity (Swanson, 1995). This instrument may offer a promising alternative to product-oriented evaluation strategies while still allowing for normative comparison.

4.09.3.3 Academic Achievement: Output

It is likely that those individuals who experience difficulties in processing or learning will display academic difficulties as well. Although some might hold that there is little difference in the measure of ability and the measure of achievement (e.g., Anastasi, 1988; Dean, 1977, 1983), it would seem that the operationalization of the two areas allows for a comparison of more generic problem-solving and verbal tasks to those directly involved in scholastic performance. Thus, a measure of ability may be conceived of as attempting to address the concept of underlying skills or capacities, whereas the measure of achievement is tied to the notion of the individual's proficiency in applying that ability in a functional way to real world skills (e.g., academics). A measure of academic achievement can help provide information as to the degree of impairment experienced by individuals, especially among children and adolescents. New learning, however, is not isolated to the school years. Adults required to learn new skills as part of job training, vocational rehabilitation, or after brain injuries are all placed in very real learning situations. It is critical to have an understanding of the client's basic skills in order to facilitate vocational, academic, and intervention decision making.

Assessment of academic achievement can occur through a blend of formal and informal measures as well. For example, in a school setting, reviewing student clients' work samples, interviewing the students and teacher about their learning and the classroom, and classroom observations can provide essential information. So too, curriculum-based measurement, where informal reading, writing, and math probes (Shinn, 1989) are obtained to determine the clients' current level of functioning and progress during intervention phases, are particularly useful for monitoring the effectiveness of treatment approaches to learning difficulties (Fuchs, 1994). There are also several types of norm-referenced instruments that are available, which, because of the availability of a standard normative base, permit comparison across a wide variety of curricular contexts (D'Amato, Rothlisberg, & Rhodes, 1997). Some of these instruments measure a particular area of achievement such as math or reading (e.g., *Keymath Revised*, Connolly, 1988; *Test of Reading Comprehension-3*, Brown, Hammill, & Wiederholt, 1995; *Test of Written Language-3*, Hammill & Larsen, 1996) while others provide a broad-based screening of a number of academic areas (e.g., *Peabody Individual Achievement Test-Revised* [*PIAT-R*], Markwardt, 1989; *Woodcock–Johnson Psychoeducational Battery-Revised* [*WJPB-R*], Woodcock & Johnson, 1989). These broad-based tests all have a similar organizational structure. For example, measures in a particular area, such as reading, are typically divided into basic skill areas (e.g., reading decoding) and some form of applied skill area (e.g., reading comprehension) so that variations in the aspects of the academic tasks can be noted. The difference between measures often lies in the method by which they obtain their information (e.g., whether visual-motor or oral responses are required); that is, whether they require the examinee to indicate the response through nonverbal (e.g., pointing) or verbal output.

The achievement test that is designed for the broadest range of individuals is the *WJPB-R* with norms ranging from 2 to 95 years of age. The *WJPB-R* consists of both a cognitive and an achievement component. The tests of achievement are divided into a standard battery consisting of four broad areas: Reading (Letter-Word Identification, Passage Comprehension), Mathematics (Calculations, Applied Problems), Written Language (Dictation, Writing Samples), and Broad Knowledge (Science, Social Studies, Humanities). A supplemental battery is also available to expand the standard battery coverage. It includes Word Attack, Reading Vocabulary, Quantitative Concepts, Proofing, and Writing Fluency. Employing one or more of the supplemental subtests gives the examiner the option of computing additional areas of achievement such as Basic Reading Skills and Reading Comprehension which is consistent with the language of the Individuals with Disabilities Educational Act of 1990 and some state legislative guidelines for identifying specific areas of learning disability. This instrument is statistically sound and ample amounts of research have been conducted and support the use of this test.

Another measure of achievement, the *PIAT-R* (Markwardt, 1989) has also been supported as a well-developed and psychometrically sound instrument (Williams & Vincent, 1991). It consists of five subtest scores (General Information, Reading Recognition, Reading Comprehension, Mathematics, Spelling) that are provided in addition to the Total Reading and Total Test scores. A Written Expression and optional Written Language score are also available. The *PIAT-R* was normed for individuals aged 5–18 years. It is different from other tests in that it includes a larger pictorial component in its item types, letting children avoid the need for verbal reply, and instead expecting them to point at the correct answer (out of four) for reading, spelling, and mathematics items. Since the task demands for recognition of information do not appear to be the same as for recall, this response format may aid children with retrieval difficulties or those that have developed some background knowledge of the area in question. It should be noted, though, that this response-type advantage may not give a good indication of the expectations for student performance in the classroom where recall and more integrated answers are the norm (D'Amato, Rothlisberg, & Rhodes, 1997).

4.09.3.4 Learning: Implications for Intervention

A number of authors have related how knowledge of the way individuals process information can contribute to the development of treatment based on neuropsychological processes (D'Amato, 1990; Reynolds, 1981b, 1986; Telzrow, 1985). For example, when learning how to read, individuals who display a simultaneous/visual spatial strength in processing might benefit from being taught using a whole word approach whereas individuals who display a strength in sequential/auditory processing can be taught using a phonetic approach (Whitten, D'Amato, & Chittooran, 1992). For both children and adults, cognitive rehabilitation is an emerging discipline which includes the retraining or use of compensatory strategies in thinking and problem-solving skills (Wedding, Horton, & Webster, 1986). Cognitive retraining can include assistance in strategy development for attention and concentration, memory, language, perceptual and cognitive deficits, and social behavior. Thus, the term cognitive retraining encompasses all areas of functioning that may have been negatively impacted by neuropsychological disorders or traumatic brain injury (D'Amato, Rothlisberg, & Leu, in press; Gray & Dean, 1989). Assisting learners with cognitive remediation or compensation often includes the use of metacognitive strategies. Metacognition includes analyzing the processes an individual uses to generate an idea or thought. By receiving assistance in breaking down problems and understanding the processes needed to solve problems, clients may learn how to generalize the process to many problem types and improve overall learning and functioning. Although cognitive retraining is time consuming, the generalizability of the strategies has been seen as appropriate to many settings (Gray & Dean, 1989; Kavale, Forness, & Bender, 1988).

4.09.4 ASSESSMENT OF SPECIAL APTITUDES

In determining the basis for a client's difficulty, it is critical to explore the building blocks of memory and learning to obtain an understanding of how the individual processes information (sensory input). For instance, sensory and perceptual skills are essential to receiving stimuli from the environment and making sense of what is received. So too, a clinician must examine the output or production that the client demonstrates in response to stimuli via action (e.g., motor skills) or communication (e.g., spoken language, writing). That is, clients may understand a task, but, because of integration difficulties or language impairments, be unable to demonstrate their knowledge. For example, the reproduction of a visual stimulus in response to a request involves both perceptual discrimination and fine motor development, as well as the ability to integrate visual, tactile, and auditory skills. Therefore, inadequate performance in copying geometric designs developed to assess these skills may stem from: a misperception, or faulty interpretation of the input information; problems in executing the fine motor response, or output; and/or difficulties integrating the input and output, otherwise known as integrative or central processing difficulties. By evaluating the domains of sensory perception, sensory-motor integration, and communication/language, the practitioner is in a better position to understand the client's ability to receive information adequately, integrate these basic skills, and demonstrate the products of memory and learning processes.

4.09.4.1 Sensory Perception

Perception of stimuli is a complex process involving many different aspects of brain functioning (Lezak, 1983). Typically, perception includes recognizing features and relationships among features. It is affected by context (figure–ground) and intensity, duration, significance, and familiarity of the stimuli (Ylvisaker, Szekeres, & Hartwick, 1994). Sensory perception skills are vital to an individual's understanding and response to the environment because they form the basis of each individual's interaction with the world (D'Amato, Rothlisberg, & Rhodes, 1997; Lezak, 1995). Difficulties may manifest themselves in the individual's ability to use information gained through the senses. For example, a client may be able to hear sounds well, but have trouble understanding what is heard (auditory processing). Likewise, a client may be able to see words clearly but have problems reproducing them when writing (visual-motor difficulties). Sensory perception tasks often form the foundation for the later performance of higher order cognitive skills. Without the ability to accurately sense and perceive cues from the environment, the learner is placed in the position of trying to decode a message when the code is scrambled and often changing.

In the assessment of sensory perception, it is important to evaluate visual, auditory, and haptic (tactile) functions. For children and older adults it is especially important that actual sensory deficits have been ruled out through the administration of a thorough vision and hearing test. If these senses appear to be intact, an in-depth evaluation of functioning is warranted. Sensory perception can be evaluated informally through clinical observations, formally through standardized tests, or via other methods of data collection. However, at times these strategies may prove inconclusive regarding the etiology of performance difficulties and more formal assessment is necessary to evaluate a client's functioning.

Several instruments are available to measure a client's functioning within this domain. Most are inexpensive and relatively quick to administer. Within the visual modality, the *Motor-Free Visual Perception Test* (*MFVPT*; Colarusso & Hammill, 1996) allows the clinician to evaluate visual perception without motor involvement in children. This 36-item measure assesses five facets of visual perception: spatial relations, visual discrimination, figure–ground, visual closure, and visual memory. The *MFVPT* is intended for children four to eight years of age. The *MFVPT* can offer information essential for the differential diagnosis of motor vs. visual processing problems. However, when used in isolation from other measures or techniques, the *MFVPT* offers information regarding visual processing difficulties but is unable to rule out motor concerns. For adults, the *Benton Revised Visual Retention Test* (Benton-Sivan, 1992) is a widely used measure of visuoperceptual ability, constructional skills, and immediate visual memory (Youngjohn, Larrabee, & Crook, 1993). Clients are required to reproduce abstract geometric designs from memory.

Some clients have difficulty discriminating sounds even when thresholds for sound perceptions are intact (Lezak, 1995). Auditory discrimination can be tested by having the client repeat words and phrases spoken by the clinician, or by asking the client whether two spoken words are the same or different. On this task, the clinician will want to use word pairs that sound alike such as "cat" and "cap" along with identical word pairs (Lezak, 1995). This technique has been formalized through the development of *Wepman's Auditory Discrimination Test* (Wepman & Reynolds, 1987) which allows the clinician to determine whether the client is able to discriminate similar sounding words adequately. Although the test was originally devised to identify auditory discrimination problems in young school children, and the present norms were developed on samples of four to eight year olds, norms for the oldest age group (8–0 to 8–11) are adequate for adults since auditory discrimination is generally fully developed by this age (Lezak, 1995).

The perception of tactile stimuli is regularly measured as a component of a thorough neuropsychological examination, but less often in nonspecialized clinical settings. Informal strategies for evaluating this area include asking clients to indicate whether they feel the sharp or the dull end of a pin, pressure from one or two points (applied simultaneously and close together), or pressure from a graded set of plastic hairs, the "Von Frey hairs" (Lezak, 1995). The eyes should be closed or the hand kept out of sight when tactile sensory functions are tested. More formal measures include the *Tactile Form Perception Test* (Benton, Hamsher, Varney, & Spreen, 1983) and the *Tactual Performance Test* (Reitan & Davison, 1974). Deficits in tactile senses are often associated with damage to the right hemisphere of the brain and may have important implications for a client's vocational functioning (Lezak, 1995).

4.09.4.1.1 Sensory perception: implications for intervention

If the client is having difficulty in one or more areas of sensory perception, this information is critical for intervention planning. That is, the client's unique pattern of receiving information from the environment can be used to create effective education, rehabilitation, or therapeutic intervention. If a client is weak in auditory processing but strong in visual processing, for example, visual cues such as drawings, videos, or demonstrations may be the most effective means for training them in new skills.

4.09.4.2 Motor: Fine and Gross

The motor domain involves a range of both fine and gross motor movement. Fine motor skill is commonly thought of as movement which does not involve the entire body. Writing, opening a letter, or tying a shoe are all examples of fine motor movements. Gross motor movement involves large extremities and often the entire body. Activities such as walking or sitting down involve gross motor capacities. Intentional movement, using fine and gross motor skills, involves a series of brain-based systems and is learned with repetition. With repeated action, the movement becomes rote or, as Luria (1973) described it, a "kinesthetic melody." Movement also can consist of both discrete and continuous patterns. Movements that are discrete might involve something as simple as lifting a finger, while continuous movements include an integrated set of skills like skipping. Movements may be disrupted if damage exists in the premotor cortex where the "kinesthetic melody" is believed to be formed. If this occurs, the individual may not be able to perform serial-continuous movements but may be able to demonstrate the specific discrete movements. Because of the complexity of motor patterns, the individual's posture, movement in isolation, and movement in serial order should be assessed for possible intervention. This can be accomplished by observing individuals completing tasks such as writing their name (uses one hand), tying their shoes (uses both hands), and also performing novel tasks such as repeated tapping or clapping patterns. It should be noted if there is difficulty integrating the use of both hands. Both fine and gross motor skills should always be evaluated.

Although informal methods will yield a great deal of information regarding a client's fine and gross motor functioning, several standardized instruments are also available which measure various specific or broad components of motoric functioning. For example, the *Bruininks–Oseretsky Test of Motor Proficiency* (Bruininks, 1978) provides a comprehensive picture of an individual's motor development. The instrument was designed for children aged 4–5 to 14–15 and can be administered in 15–60 minutes, depending on whether the complete or short form of the battery is used. Three composite scores are provided in the areas of: Gross Motor Development (Running speed and agility, Balance, Bilateral coordination, Strength), Gross and Fine Motor Development (Upper-limb coordination), and Fine Motor Development (Response speed, Visual-motor control, Upper-limb speed and dexterity). Specific fine motor abilities can also be measured by using the Finger Tapping Test and the Grip Strength Test which are both a part of the Halstead-Reitan Battery (Reitan & Wolfson 1993).

To measure a client's lateral preference, the *Lateral Preference Schedule* (Dean, 1988) can be administered to obtain a better understanding of clients' lateral preference in the use of their eyes, ears, arms, hands, and feet (Rothlisberg, 1991). Atypical patterns of lateral preference have been hypothesized to indicate potential predictors of reading difficulty (Bemporad & Kinsbourne, 1983; Dean, Schwartz, & Smith, 1981). Determining lateral preference can be useful in interpreting assessment findings and in creating a plan for rehabilitation (Lezak, 1995).

4.09.4.3 Sensory-motor Integration

An additional component of our motoric functioning is the ability to integrate what is received by the senses with what is produced through action. For example, an individual may be able to perceive letters correctly and have adequate fine motor control, but still have difficulty correctly copying material presented in visual form. Numerous paper-and-pencil tests have been developed to assess motor function as it relates to visual-motor integration. Two of the most popular measures for this purpose are the *Bender Visual-Motor Gestalt* (Bender, 1938) and the *Developmental Test of Visual-Motor Integration* (*VMI*; Beery, 1989).

The *Visual-Motor Gestalt Test* (Bender, 1938) is an individually administered test containing nine geometric figures which the client copies on to a blank sheet of paper. While historically this test was seen as a general measure of organicity, it is more appropriately used as a measure of visual-motor skills. Standard scores are provided in the developmental scoring system for children ages 5–0 to 11–11, although it is frequently used with adults as well. Most commonly known as the "Bender," this measure is perhaps the best known and most widely used visual-motor assessment procedure available today (Bender, 1938; Reynolds & Kamphaus, 1990). As a component of a comprehensive assessment battery, performance on the Bender has long been thought to reveal visual-motor difficulties that may be associated with cerebral impairment (Sattler, 1992). Traditionally used to assess an individual's constructional praxic skills, the Bender provides an evaluation of motor integration employed in the execution of complex learned movements (Hartlage & Golden, 1990). The information generated through this process may then be compared with levels of performance across other measures of functioning.

Alternate uses of the Bender include its administration as a memory test as well as a copying test. This dual administration process can be employed to assess different mental functions (short-term visual memory and visual perception) which utilize the same modalities in perception and task execution (Sattler, 1992). An additional technique available when interpreting the Bender performance is to have individuals compare the figure which they produced with the corresponding stimulus design. If the client is unable to recognize obvious differences between the two designs, a perceptual deficit may be involved. Likewise, if the client is able to detect a difference between the two figures, but is unable to make them alike, motor involvement may be influencing performance (Hartlage & Golden, 1990). In the personality area, performance on the Bender may also be used to develop hypotheses regarding impaired performance due to poor planning, impulsivity, or compulsivity. Extremely large or small figures, heavily reinforced lines, and second attempts are examples of the item reproduction difficulties which are thought to indicate emotional concerns on the part of the individual.

The *VMI* is an individual or group administered test that involves copying a sequence of 24, increasingly complex, geometric figures. The test requires a relatively short administration time and is designed primarily for ages 4 to 13. The *VMI* offers several advantages as a tool for assessment and is widely used in psychological evaluation and research. The most common use of the *VMI*, now in its third edition, seems to be in assisting with the diagnosis of children who are suspected of having learning problems due to visual-motor difficulties. The *VMI* is also frequently employed when investigating the reliability and validity of other tests of visual-motor integration, such as the Bender, self drawing tasks, progressive matrices, and neuropsychological tests (Goldstein, Smith, & Waldrep, 1986; Palisano & Dichter, 1989). Because the *VMI* does not require a verbal response, it has also been used to assess visual-motor processes among non-English-speaking children (Brand, 1991; Frey & Pinelli, 1991).

4.09.4.3.1 Motor: implications for intervention

Motor problems and sensory-motor integration difficulties can impair a client's ability to write or to learn new skills requiring motor coordination, and generally can have a negative impact on daily functioning. In the classroom setting, possible suggestions for accommodating these difficulties might include modifying instructions to compensate for motor difficulties (e.g., allowing pointing to the correct choice rather than writing, allowing students to tape record notes or copy them from others). In a rehabilitation setting, the client may need to learn alternative methods for writing such as using word processing programs on a computer or, if serious difficulties exist, using voice-activated programs. Consultation with an occupational therapist or a physical therapist will be extremely helpful in treatment planning when motor difficulties are evident.

4.09.4.4 Communication/Language

Language is the basic tool of human communication and hence essential to evaluate when working with any client (Black & Strub, 1994). It should be viewed as a key skill because it serves as a primary means of conveying information from the individual to others and from others to the individual. Thus, communication difficulties have the power to influence all areas of life (D'Amato, Rothlisberg, & Rhodes, 1997). Difficulties or dysfunction found on tests of higher level functioning (e.g., learning processes) may well be secondary to a language disorder. Accordingly, language should be evaluated early in the course of an assessment to rule out problems in this area of functioning (Black & Strub, 1994; Lezak, 1995). Another obvious reason to evaluate language and communication skills is that language disorders occur as the result of a wide range of neurologic diseases and can manifest in a variety of forms of aphasia (e.g., Wernicke's, anomia, global, alexia, agraphia; Kolb & Whishaw, 1990). To aid in the interpretation of test findings, it is important for the clinician to be familiar with the various classic clinical aphasia presentations (see Gaddes & Edgell, 1994; Kolb & Whishaw, 1990; Lezak, 1995).

The language evaluation should be systematic and include an assessment of a range of relatively specific language functions. Assessment must evaluate both receptive and expressive verbal and nonverbal abilities to determine if adaptations are needed to enhance the individual in academic, vocational, and social situations. As part of an informal evaluation of expressive language, the clinician will want to evaluate spontaneous speech and verbal fluency by asking the client open-ended questions (Black & Strub, 1994). While the client is responding, the clinician can listen carefully for abnormal articulation, dysarthria (incoordination of the speech apparatus), verbal apraxia (difficulty carrying out purposeful speech), dysfluency, loss of prosody (melodic intonation), and disturbances of syntax or paraphasic errors (production of unintended syllables, words, or phrases) (Black & Strub, 1994; Kolb & Whishaw, 1990). Another important component of language, pragmatics, can also be evaluated. Pragmatics refers to the knowledge and activities of socially appropriate communication, which takes in much of the nonverbal aspects of communication, such as gestures, loudness of speech, as well as verbal appropriateness (Sohlberg & Mateer, 1990).

Evaluation of verbal fluency can be accomplished by counting the number of words the client is able to produce without repetition within a restricted category (e.g., animals or words beginning with a particular letter) and time (e.g., 60 seconds). The average adult should produce approximately 20 animal names and a total of 40–60 words with performance depending to some degree on the client's intelligence, education, and social/linguistic background (Black & Strub, 1994). Additional methods of examining expressive language include having the client repeat back meaningful verbal phrases or sentences of increasing length and semantic complexity. Word finding and naming difficulties can be detected by the client's responses to the open-ended questions or by having the client describe a picture containing a series of objects or actions (Black & Strub, 1994).

Another major area of language functioning is receptive language or an individual's ability to understand what has been said. A comprehensive assessment should include an evaluation of the individual's ability to analyze and integrate information presented in a verbal format, since a common difficulty among those experiencing traumatic head injury is a decreased capacity to coordinate the social aspects of language (Ylvisaker, Szekeres, Haarbauer-Krupa, Urbanczyk, & Feeney, 1994). It is not sufficient to evaluate language comprehension based on open-ended questions because this method relies on expressive skills and does not examine comprehension in isolation (Black & Strub, 1994). Language comprehension can be evaluated informally by asking the client to point to common objects in the room or by asking a series of increasingly complex questions that require only a "yes" or "no" response (e.g. "Do dogs have four legs?") (Black & Strub, 1994). An evaluation of a client's reading and writing skills could also be included in an evaluation of language and communication (Black & Strub, 1994). The client can be asked to read sentences of increasing difficulty, spell words to dictation, and compose a paragraph in response to a prompt (e.g., "Tell me how to change a tire.") (Black & Strub, 1994).

In addition to the informal methods, several instruments are available that can prove useful for the clinical evaluation of language. There are a number of aphasia tests and batteries (e.g., *Boston Diagnostic Aphasia Examination*, Goodglass & Kaplan, 1983; *Multilingual Aphasia Examination*, Benton & Hamsher, 1989) which involve lengthy, well-controlled procedures and are best left to speech pathologists who have more extensive training in the specialized techniques of aphasia examinations (Lezak, 1995). As an alternative, aphasia screening tests can be used to indicate the presence of an aphasic disorder and may even highlight its specific characteristics, but do not provide the fine discriminations of the complete aphasia test batteries. Furthermore, these screening tests do not require technical knowledge of speech pathology for adequate administration or determination of whether a significant aphasic disorder is present (Lezak, 1995). One of the most comprehensive aphasic screening tests available is the *Revised Token Test* (McNeil & Prescott, 1978). This expanded version of the original *Token Test* (De Renzi & Vignolo, 1962) contains 10 10-item subtests. McNeil and Prescott (1978) sought to ameliorate psychometric weaknesses of the original with this revision as well as seeking to develop an evaluative system for describing the nature and quantifying the degree of language deficit in order to facilitate treatment planning. Using tokens of various shapes and sizes, the clinician gives the client a series of increasingly complex instructions to follow. Though simple to administer, this instrument is reportedly very sensitive to disrupted linguistic processes that are central to the aphasic disability (Lezak, 1995).

Clinicians wanting a basic measure of different aspects of communication and language may wish to consider using the *Peabody Picture Vocabulary Test-Revised* (*PPVT-R*; Dunn & Dunn, 1981), the *Test of Language Development* (*TOLD-2*; Hammill & Newcomer, 1988), and the *Clinical Evaluation of Language Fundamentals-Revised* (Semel, Wiig, & Secord, 1987) or the *Test of Language Competence* (*TLC*; Wiig & Secord, 1989). Unfortunately, most of these tests are normed exclusively on children and adolescents and, therefore, have limited application to adults. One of the most frequently used tests, and one which has adult norms, is the *PPVT-R*. This test measures receptive vocabulary only and was normed for individuals aged two and a half to adulthood. The *PPVT-R* is untimed and requires the examinee to select from each plate of four pictures the one that best represents the target word. The test requires no reading ability, nor is the ability to point or provide an oral response essential (Shea, 1989). The *PPVT-R* can help to establish the level of verbal understanding a client has when expressive language is not required. Comparing such receptive skills with those expressive skills needed for other tests may help in developing hypotheses about the qualitative nature of verbal performance and in framing potential treatment (D'Amato, Rothlisberg, & Rhodes, 1997).

The *TOLD-2* is available in a form designed for primary ages (4–0 to 8–11) and intermediate ages (8–6 to 12–11). This test purports to measure receptive and expressive language proficiency. The results for the *TOLD-2* provide quotients for an Overall Spoken Language score, and for the composites of Listening, Speaking, Semantics, Syntax, and Phonology (on the primary form only). Overall, the *TOLD-2* instruments are reliable and valid as language screening tools for younger clients (Wochnick Fodness, McNeilly, & Bradley-Johnson, 1991; Westby, 1988). Some tests have been developed to measure more complex language usage, such as the TLC (Wiig & Secord, 1989) which purports to measure metalinguistic abilities. The four subtests involve producing multiple meanings for ambiguous sentences, recognizing inferences on the basis of incomplete information, creating sentences given three words and a context, and recognizing the meaning of figurative language. This type of test may be useful for identifying subtle problems in language usage (Crosson, 1996).

4.09.4.4.1 Communication/language: implications for intervention

For clients who are experiencing difficulty with either or both receptive and expressive language, the clinician can modify verbal interaction by shortening the length of information presented or presenting information in steps. Additional ideas for the school-age client might include recommending that the teacher repeat directions and have the student also repeat and explain the directions back to the teacher, pairing verbal instructions with nonverbal cues, and using nonverbal cues. Many of these strategies could be adapted to adults in rehabilitation and other types of therapeutic settings as well. The clinician must be careful to check frequently with clients to ensure understanding and to assist the clients and their families to adjust to these communication or language deficits.

4.09.5 FUTURE DIRECTIONS

Although knowledge about how individuals process information has grown exponentially since the late 1970s, researchers and practitioners alike are left with many questions regarding how individuals remember and learn. How do age, gender, and ethnicity impact a client's functioning on these specific instruments? Do individuals with brain damage process information differently than individuals with "normal" brain functioning? How do the results of an assessment translate into effective treatment strategies that will help individuals function better on the job? Despite these questions and more, as a field we do know that current measures of processing can allow practitioners to make predictions with a reasonable level of confidence. However, we must also recognize that future research investigating the prediction accuracy of various tests is needed to expand the range and precision of clinical prediction (Long, 1996). Indeed, limited research exists that evaluates the effect of various treatment approaches on success in clinical pediatric or adult populations (Batchelor, 1996b; Ris & Noll, 1994). As our knowledge of the nervous system is expanded, and we begin to understand the intricacies of the brain's organization, we can begin to see how perceptions are formed, information stored and integrated, and action taken. Until that time, the explanation for behavior and certain learning difficulties can only be inferred (D'Amato, Rothlisberg, & Leu, in press).

Another component complicating our enhanced understanding of information processing is the need for common language and goals between neurologists, psychologists, educational researchers, and vocational rehabilitation specialists. Bigler (1996) notes that it is

> essential that physicians and psychologists work toward some common understanding of normal and abnormal behavioral manifestations of brain functioning, particularly aspects of complex attention and integration of sensory experiences, memory, motivation, organization of verbal and nonverbal cognition, abstract thinking, problem solving, executive functions, and self-monitoring of behavior. Without agreement on a detailed and relatively comprehensive model of neurobehavioral development, psychologists will be limited in their ability to develop appropriate assessment and intervention strategies. (p. 50)

Unfortunately, outcomes in rehabilitation research have also suffered from a lack of consensus with importance placed on different variables depending on the orientation of the author and audience (Batchelor, 1996b). For example, clinical researchers have examined pre- and postperformance measures of cognitive, motivational, and behavioral functions (Ris & Noll, 1994), while service providers have focused on outcome constructs such as employment and independent living (e.g., Adunsky, Hershkowitz, Rabbi, Asher-Sivron, & Ohry, 1992). Concurrently, third-party payers are interested in length of stay, cost, and effectiveness in allocation of resources (Fratalli, 1993), while families and consumers are interested in quality of care. Batchelor (1996b) concluded that the majority of research has emphasized short-term outcomes and the meaningful questions generated by service providers, consumers, and third-party payers have been overlooked and present an important direction for the field to pursue.

In terms of the practical aspects of assessment, the practitioner's task is not an easy one. In order to generate an accurate diagnosis or provide the most sound recommendations, a complete understanding of the client is necessary. A practitioner could spend hours evaluating each of the areas outlined with careful consideration of all subdomains using a multidimensional approach. Although this approach would yield a bounty of information, it may not be practical given time limitations and insurance policy guidelines. The key for the clinician is to find a balance between finding out the most important information about client functioning through the use of instruments with the best predictive ability and spending a limited amount of time on assessment. By creating an efficient and effective assessment approach, more time is available to implement treatment. The task of generating recommendations for interventions that are likely to enhance client functioning is of central importance to the issue of assessment. To this end, continued information is needed on the relationship between assessed cognitive processing and predicted future performance in real-world settings (Sbordone & Long, 1996). Furthermore, we must gain knowledge about the most effective intervention strategies for all types of individuals. Future research will enable us to understand how the brain processes information and what treatments are effective with what types of clients. Indeed, this additional knowledge may allow us to match client subtypes with specific treatments which will increase the effectiveness and efficacy of psychological services.

4.09.6 SUMMARY

The assessment of children, adolescents, and adults encompasses a wide range of domains from which a clinician may view a client's functioning. Consideration must be given to the many layers of the client context (e.g., family support, socioeconomic status, domain of functioning), client characteristics (e.g., motivation, education level, ethnicity, age), as well as the specific cognitive processes under question (e.g., memory, sensory perception). Although often overlooked or subsumed within the broader arenas of intelligence or achievement, the specific areas of memory, learning, and special aptitudes are critical to our daily functioning. That is, one will have difficulty demonstrating intelligence or learning new tasks, if there is a severe memory deficit or difficulty in accurately perceiving stimuli. The descriptions of the domains presented in this chapter have offered insight into the field's current understanding of these systems as well as the breadth of evaluation strategies available to probe the diverse nature of cognitive processes. Once the practitioner identifies the assessment needs of the individual client, and a decision is made as to the components most relevant for exploring the referral question, the process can begin. By generating quality data, our ability to predict outcomes and provide effective potential intervention strategies is increased. Indeed, the goal of any assessment is to respond correctly to the question presented by the referral source, provide accurate predictions of future outcomes, and generate effective strategies for improving the client's adaptation or functioning.

4.10.1 INTRODUCTION

The area of clinical neuropsychology has only recently been established as a viable specialty area (Woody, 1997). By definition, neuropsychology is the study of brain–behavior relationships that uses the theory and methodologies of both neurology and psychology. Historically, neuropsychology has been used for the diagnostic assessment of adults with known brain damage or injury; the clinical research has been derived from the study of adults with identified insult to the brain. The major premise of neuropsychological assessment is that different behaviors, including higher order cognitive skills, involve differing neurological structures or functional systems (Luria, 1980). As such, the neuropsychological approach to assessment involves assessment of various behavioral domains believed to be related to functional systems and making inferences about brain integrity based on the individual's performance across these domains. Neuropsychological assessment samples behaviors known to depend on the integrity of the central nervous system (CNS) using measures that correlate with cognitive, sensorimotor, and emotional functioning based on clinical research (Dean & Gray, 1990).

As more became known about brain–behavior relationships, clinical findings and theories were applied to the understanding of learning and behavior problems of adults where brain damage/injury was not identified. Thus, neuropsychological assessment as it is practiced today grew out of the need to clarify pathophysiological conditions where brain damage was not indicated by neurological, neuroradiological, or electrophysiological methods, in order to make differential diagnoses and provide information that would be useful in treatment planning and follow up (Dean & Gray, 1990). Based on the neuropsychological study of adults, this progressed to the application of neuropsychological methods and perspectives to the understanding of learning and other problems in children (L. C. Hartlage & Long, 1997).

Luria's (1970, 1980) theory, while based on adults, can be applied to children and adolescents. Neuropsychological techniques have been incorporated into the assessment of children for special education for some time (e.g., Haak, 1989; Hynd, 1981) with increasing interest by neuropsychologists in educational problems such as learning disability and attention deficit hyperactivity disorder (ADHD). The influence of theories specific to child psychology, school psychology, and education, are evident in the composition of neuropsychological assessment batteries, procedures, and measures used with children (Batchelor, 1996a). Increased interest and emphasis in the application of neuropsychology to educational issues and children may be due to a variety of factors: the emergence of clinical neuropsychology as a specialty area; advances in neuroscience and clinical evidence, specific to brain–behavior relationships, based on localized brain damage in childhood and youth; advances in technology (e.g., functional imaging) that are adding to the knowledge base regarding brain development and function; and continued research efforts specific to problems encountered by children and their neuropsychological functioning.

Several positive outcomes of the application of neuropsychology to children and adolescents have been identified. These include extending the range of diagnostic techniques available, providing for better integration of behavioral data (Dean, 1986; Gray & Dean, 1990; Obrzut & Hynd, 1983), increasing the ability to deal adequately with the multidimensionality of observed behavior, creating a unified or holistic picture of a student's functioning (Rothlisberg & D'Amato, 1988), and providing documentation of changes in behavior and development (Hynd & Willis, 1988). Clinical child neuropsychology provides a theoretical framework for understanding identified patterns of strengths and weaknesses, the relationships between strengths and weaknesses, and the extent to which these patterns remain stable or are subject to change over the course of development (Fletcher & Taylor, 1984; Temple, 1997). Increased understanding of the child's strengths and weaknesses can potentially be used to identify areas that may provide difficulty for the child in the future, as well as compensatory strategies or methods to circumvent these difficulties. It has further been argued that neuropsychological assessment of children can provide a better understanding of the ways in which neurological conditions impact on behavior and the translation of this knowledge into educationally relevant information (Allen, 1989). Although not all psychologists agree with the application of neuropsychological principles to children (see Riccio, Hynd, & Cohen, 1993), the growing significance of clinical child neuropsychology is evident in the increasing number of child clinical and school psychology graduate programs that offer coursework in neuropsychology (e.g., D'Amato, Hammons, Terminie, & Dean, 1992).

As a result of this growing interest in clinical child neuropsychology, the extent of knowledge available regarding the developing brain has increased dramatically since the 1980s. This includes advances in the understanding of typical development of neuropsychological functions (e.g., Ardila & Roselli, 1994; Halperin, McKay, Matier, & Sharma, 1994; Miller & Vernon, 1996; Molfese, 1995). Research has also begun to explore physiological processes and subcortical motivational systems that, together with environmental influences, are believed to impact on how the relevancy of information is determined and, ultimately, on the formation of cognitive representations in typically developing children (Derryberry & Reed, 1996). Additional advances in educational arenas have been made in the understanding of learning disabilities (e.g., Feagans, Short, & Meltzer, 1991; Geary, 1993; Obrzut & Hynd, 1983; Riccio, Gonzalez, & Hynd, 1994; Riccio & Hynd, 1995, 1996) as well as in the understanding of the short- and long-term problems associated with traumatic brain injury (e.g., Bigler, 1990; Snow & Hooper, 1994); the sequelae of neurological impairment of known causes such as lead poisoning, meningitis, and so on (e.g., Bellinger, 1995; Taylor, Barry, & Schatschneider, 1993); the impact of cancer treatment on CNS function (e.g., Copeland et al., 1988); and the short- and long-term sequelae in children identified as at-risk for learning problems due to perinatal or prenatal difficulties (e.g., Breslau, Chilcoat, DelDotto, & Andreski, 1996; Cohen, Beckwith, Parmalee, & Sigman, 1996; Gatten, Arceneaux, Dean, & Anderson, 1994; Saigal, 1995; Waber & McCormick, 1995).

While more research has focused on educational problems, increased risk for psychiatric disorder and long-term adjustment problems have been found to be associated with brain injury, both in adults and children (e.g., Breslau & Marshall, 1985; Rutter, Graham, & Yule, 1970; Seidel, Chadwick, & Rutter, 1975). Research consistently demonstrates that adjustment and behavioral problems are associated with children who have neurodevelopmental deficits (e.g., Hooper & Tramontana, 1997; Tramontana & Hooper, 1997). Children with neurological impairment have been found to be six times more likely to develop emotional, behavioral, or motivational problems secondary to, if not as a direct result of, the neurological impairment (Dean, 1986). At one time it was believed that specific relationships between brain dysfunction and child psychopathology would be found; it is now posited that the relationships between brain integrity and psychopathology are nonspecific and impacted by secondary influences including failure, frustration, social stigma, family reaction, and so on (Tramontana & Hooper, 1997). Many advances have been made in the area of psychopathology, including the development of models specific to the underlying neurological basis of ADHD (see Riccio, Hynd, & Cohen, 1996), autism (e.g., Damasio & Maurer, 1978; Hooper, Boyd, Hynd, & Rubin, 1993; Hurd, 1996; Maurer & Damasio, 1982; Shields, Varley, Broks, & Simpson, 1996), schizophrenia in childhood and adolescence (e.g., Asarnow, Asamen, Granholm, & Sherman, 1994; Asarnow, Brown, & Strandburg, 1995; Hendren, Hodde-Vargas, Yeo, & Vargas, 1995), conduct disorder (e.g., Moffitt, 1993), and anxiety (e.g., Gray, 1982). Various models (e.g., Gray, 1982; Kinsbourne, 1989; Nussbaum et al., 1988; Rourke, 1989; Tucker, 1989) have been proposed to explain the interface between brain function and behaviors associated with childhood psychopathology.

This chapter will provide an overview of the neuropsychological assessment process for children, both historically and in the context of current practices and future trends. Continuing concerns with regard to the translation to children and adolescents of what is known about adult functioning and neuropsychological assessment, as well as concerns with measurement and methodology, will be discussed. Finally, future directions and issues that need to be addressed in the neuropsychological assessment of children, if clinical child neuropsychology is to continue to add to the understanding of underlying processes in children's learning and behavior, as well as the application of that understanding to intervention programs, will be addressed.

4.10.1.1 Assessment Process

Neuropsychological assessment generally includes assessment of a number of functional domains that are, based on clinical evidence, associated with functional systems of the brain. This is considered important for the development of hypotheses and potential interventions (L. C. Hartlage & Telzrow, 1986; Whitten, D'Amato, & Chitooran, 1992). Areas evaluated generally include cognition, achievement, and behavior/personality/emotionality, as would be assessed as part of a general psychological evaluation. A neuropsychological evaluation provides for consideration of a wider array of functions, however, than is addressed in a typical psychological or psychoeducational evaluation (Dean, 1985, 1986; Obrzut, 1981). In general, the neuropsychological evaluation is more thorough and also includes the assessment of perceptual, motor, and sensory areas, and of attention, executive function (planning, organization), and learning/memory (e.g., Dean & Gray, 1990; Obrzut, 1981; Shurtleff, Fay, Abbot, & Berninger, 1988).

Given that the neurodevelopment of Luria's functional systems and the experiences of the child interact in a reciprocal manner (Spreen, Risser, & Edgell, 1995), as well as the potential for adjustment/behavioral difficulties, the use has been advocated of a transactional model that takes into consideration the reciprocal interactions of the child, home and family members, classroom (teacher and peers), and other social environments in which the child functions (Batchelor, 1996b; D'Amato & Rothlisberg, 1996; D'Amato, Rothlisberg, & Leu, in press; Teeter, 1997; Teeter & Semrud-Clikeman, 1997). This should incorporate information from a variety of sources (e.g., parents, teachers, physicians, medical records, school records, and so on) in order to enable cross-comparison (Batchelor, 1996b). In addition, it has been suggested that motivational factors (Batchelor, 1996b) and the child's ability to cope with the injury/impairment need to be determined (Dean, 1986). Thus, the neuropsychological assessment process not only incorporates a more complete review of information regarding the child but attempts to integrate this information with an understanding of brain–behavior relations and environmental factors (Taylor & Fletcher, 1990).

This means that a neuropsychological assessment involves a wide range of tasks focused on the child, as well as measures/observations of the various contexts in which the child functions and the associated expectations. Some critics of neuropsychological assessment have argued that so extensive an evaluation is not time- or cost-effective (e.g., Little & Stavrou, 1993). For example, neuropsychological assessment of a learning disability goes beyond identifying the academic deficit(s) to the identification of the child's processing strengths and deficits as well as the child's ability to function in a variety of contexts (Morris, 1994). The assessment of a wider range of higher cortical functions is supported by research findings that neurological disorders are seldom expressed as a single dysfunction (Dean & Gray, 1990), and it has been shown to improve differential diagnosis of learning problems (D'Amato, Rothlisberg, & Rhodes, 1997; Morris, 1994; Rourke, 1994). It is further argued that the process of deriving hypotheses for intervention planning is a complex process that requires a comprehensive assessment battery coupled with neuropsychological foundations and familiarity with the contexts and task demands of the child (Gaddes, 1983; Rourke, 1994). The cumulative performances of the child on neuropsychological measures are seen as behavioral indicators of brain function (Fennell & Bauer 1997). Based on all of the data generated in the evaluation process, hypotheses are generated which are specific to how and why a child processes information (D'Amato, 1990; Dean 1986; Leu & D'Amato, 1994; Whitten et al., 1992). Inferences are then made based on the child's performance on a variety of measures and the theoretical perspective of the clinician.

Much of the skepticism regarding the application of neuropsychology to problems of learning and behavior in children has centered on the assessment–intervention interface (Little & Stavrou, 1993; Samuels, 1979; Sandoval & Halperin, 1981). It is argued by some that neuropsychological perspectives do not add to the ability to develop remedial and treatment programs and may even lead to a sense of hopelessness (Little & Stavrou, 1993). Others have argued that the information obtained from neuropsychological assessment can be used as the basis for developing appropriate intervention programs (Gaddes & Edgell, 1994; Reynolds, 1981b; Rourke, 1991, 1994; Teeter & Semrud-Clikeman, 1997). Data about the additional areas of functioning included in the neuropsychological assessment are needed to support inferences about the integrity of various functional systems of the brain (Shurtleff et al., 1988). The neuropsychological perspective leads to better understanding of underlying causes of learning and behavior problems; this in turn results in an increased ability to develop appropriate interventions or circumvent future problems (D'Amato et al., 1997).

Ultimately, data generated from the neuropsychological assessment process are used to develop recommendations regarding whether the individual would profit from compensatory strategies, remedial instruction, or a combination of approaches (Gaddes & Edgell, 1994). Through the use of information about how various skills correlate in the developmental process, neuropsychological assessment allows one to make inferences not only about those skills measured, but also about skills that have not been evaluated. Further, by understanding the neurological correlates of these skills and of instructional methods, neuropsychological assessment can assist in the formulation of hypotheses regarding potential instructional methods/materials for a particular child (Reynolds, Kamphaus, Rosenthal, & Hiemenz, 1997). For example, based on the neuropsychological evaluation of two children with autism, differing nonverbal teaching strategies were identified for each child in order to improve their individual outcomes (Hurd, 1996).

While "treatment" within the framework of education is generally considered to consist of eligibility, placement decisions, and the development of an educational plan, "treatment" resulting from a neuropsychological assessment frequently includes assistance with specific medical management, vocationally related goals, speech/language areas, and physical issues (Cohen, Branch, Willis, Weyandt, & Hynd, 1992; Dean & Gray, 1990). Effective interventions need to take into consideration the myriad psychosocial contexts in which the child functions and adjustment and motivational issues, and to identify those environmental modifications that can ameliorate or reduce the behavioral effects of brain dysfunction (Batchelor, 1996b; Teeter & Semrud-Clikeman, 1997). It has been suggested that the interventions developed must also be multidimensional and incorporate not only academic, behavioral, and psychosocial techniques, but also include motivational, metacognitive, medical, and classroom management techniques (Batchelor, 1996b; Teeter & Semrud-Clikeman, 1997). However, correct diagnosis and early implementation of treatment strategies that work have been shown to be cost-effective in dollars and in the quality of a child's life (Reynolds, Wilen, & Stone, 1997).

4.10.2 MEASURES USED IN THE ASSESSMENT OF CHILDREN

As previously noted, the application of neuropsychological theory and assessment with children was derived from applications with adults. In the development of clinical child neuropsychology, historically, one of the basic avenues used in determining the assessment measures and processes to be used consisted of modifying, for use with children, existing neuropsychological batteries and other measures already used for adults (L. C. Hartlage & Long, 1997). In some cases, this involved modifying some tasks in the battery or adding tasks. An alternative strategy involved collecting some normative data on children for existing tasks. Both of these strategies were based on the clinical efficacy of the measures with adults, not with children, and on the assumption that tasks for adults measure the same thing when used with children. Similarly, in the assessment and hypothesis generation process, it is tempting to assume that neuropsychological findings from adults will be useful with children; however, this has not been shown to be a valid assumption.

When applied to children and adolescents, the premise that behavior can be used to make inferences about brain function and integrity has to be expanded to include consideration of neurodevelopmental differences that exist as a function of the age of the child. To directly apply adult inferences/hypotheses to children ignores what is known about changes in the functional organization of the brain as children grow (Cohen et al. 1992; Fletcher & Taylor, 1984). Research has provided evidence of age-based differences in children for verbal memory (Kail, 1984; Miller & Vernon, 1996), language (Segalowitz, 1983) and right hemisphere functions (Bakker, 1984; Wittelson, 1977). Recent research, for example, found that the relationship of memory, general intelligence, and speed of processing in children was not consistent with adult models (Miller & Vernon, 1996). Research has also suggested that typologies generated from the Halstead–Reitan Neuropsychological Battery (HRNB) used with children differed from typologies generated with adults, in that the child groups were more homogeneous, but provided less coverage (28–42%) as compared to adult typologies (Livingston et al., 1997). Because of neurodevelopmental changes, it is also not possible to view brain dysfunction on a continuum based on behavioral deficits as these may change over time (Fletcher & Taylor, 1984).

Further, there is often an over-reliance on signs of dysfunction in adults as reflecting pathology in children when these may be developmental. For example, on clock-face drawing in adults, identification of unilateral spatial neglect has been of particular interest (e.g., Heilman, Watson, & Valenstein, 1985; Mesulam, 1985). Developmental study of clock-face drawing with children found that this hemispatial neglect was developmental and not infrequent through the age of seven years (Edmonds, Cohen, Riccio, Bacon, & Hynd, 1993). It was concluded that this developmental pattern was consistent with the development of the frontal lobes and planning ability in children.

Neurodevelopment follows an ontogenetic course with primary cortical zones generally mature by birth (Luria, 1980). Secondary and tertiary areas continue to develop postnatally. These include the integrative systems involved in the higher order functions of learning, memory, attention, emotion, cognition, and language as well as the association areas. The association areas are the last of these areas to develop and myelinate (Goldman & Lewis, 1978; Goldman-Rakic, 1987). Vygotsky (1980) suggested that not only is there continued development of secondary and tertiary areas, but that the interaction of primary, secondary, and tertiary areas is likely to change with chronological age (Merola & Leiderman, 1985; Rutter, 1981). Although the developmental sequence for the formation of neural pathways and the myelination of specific locations corresponding to specific behaviors have been identified, these do not correspond directly to models of cognitive development (Spreen et al., 1995).

Knowledge of typical neurodevelopmental progress has increased since the 1980s; however, most of what is practiced today, as well as the theoretical bases in neuropsychology, is grounded on observations and informal assessment of individuals with identified brain damage (Reynolds, 1997b). Extensive research regarding typical neurodevelopment, particularly in relation to higher order cognitive skills, is limited, and the changing organization over time of brain function in children is only beginning to be understood (Hynd & Willis, 1988). Thus, there are still many unanswered questions regarding the developmental progression of many functional systems, particularly at the associative and integrative levels, and concerning how the neurodevelopmental progression maps onto the cognitive functioning observed.

It is often assumed, for example, based on earlier theory, that children reach adult levels of performance at 8–10 years of age. For example, Luria (1966) suggested that the frontal lobes become functional between the ages of four and seven years. This in turn led to the assumption that executive functioning would approach adult levels by age 8–10 years. It has been suggested that the greatest period of frontal lobe development occurs at the six- and eight-year-old levels, which is consistent with Luria's initial hypothesis (Passler, Isaac, & Hynd, 1985). Subsequent research, however, has demonstrated that the development of frontal lobe functioning continues at least through age 12 and possibly through age 16 (e.g., Becker, Isaac, & Hynd, 1987; Chelune & Baer, 1986; Levin et al., 1991; Welsh, Pennington, & Grossier, 1991). Further, while cognitive ability does not appear to be a factor for particular measures of frontal lobe functioning after age 12, it has been suggested that cognition can impact performance on frontal lobe measures in younger children (Chelune & Thompson, 1987; Riccio, Hall, et al., 1994). Thus, it is important to first have a strong foundation of understanding of the normal neurodevelopmental course before it is possible to interpret accurately and differentiate behaviors that represent an alteration or deviance from expected neurodevelopment.

Not only do neurodevelopmental courses need to be considered, there are complex differences between children and adults in the mechanisms of brain pathology that lead to neuropsychological and behavioral/affective problems and these do not necessarily follow a similar progression in children as for adults (Fennell & Bauer, 1997; Fletcher & Taylor, 1984). The developing brain of the child needs to be considered in that the impact of neurological insult is influenced by age as well as location and nature of injury, gender, socioeconomic status, level of emotional adjustment and coping, and the individual's own adaptive skills (Bolter & Long, 1985). With the development of the child occurring on a continuous basis and at a rapid rate, it is often difficult to obtain sufficient consistency from the premorbid history (Batchelor, 1996a). Accurate estimation of premorbid ability levels is best obtained from previous individualized standardized cognitive or achievement assessment, or if this is unavailable, from results of group-administered standardized data from school records with some consideration for potential regression effects (Reynolds, 1997c). For young children, this information is not generally available. Prenatal and perinatal, as well as postnatal developmental histories may be inaccurate, incomplete, or unknown, particularly in very young children (Batchelor, Gray, Dean, & Lowery, 1988; Gray, Dean, & Rattan, 1987). Even in school-aged children, teacher reports, grades, and so on may result in inaccurate estimations of premorbid ability (Reynolds, 1997c).

Given the different mechanisms and progression involved in the pathology, it is clear that the inferences drawn from and the interpretations of neuropsychological performance need to be different for adults and children. For children, the nature and persistence of learning problems is dependent on the status of development of various brain structures, the effects of the injury/insult, and the interactions between functional and dysfunctional neurological systems, as well as genetic and environmental influences (Teeter & Semrud-Clikeman, 1997).

Neuropsychological assessment of children and adolescents requires not only tests/measures that are age-appropriate and have sufficient empirical support for the inferences being made between neurological substrates and the behavioral performance of the child, but the generation of inferences also needs to take into consideration these developmental issues (Cohen et al., 1992). Further, it is important to document the sensitivity of the measures to neurobehavioral and neurodevelopmental functioning in children (Fletcher & Taylor, 1984). Although the measures are derived predominantly from neuropsychological study and clinical evidence regarding adults with known brain injury, a developmental perspective needs to be maintained in the application of neuropsychology to children (Hooper & Tramontana, 1997). Unfortunately, many of the measures used with adults do not have the sensitivity necessary to reflect developmental issues and, as a result, the utility of procedures used with adults in the neuropsychological assessment of children has multiple pitfalls and has been questioned (e.g., Cohen et al., 1992; Fletcher & Taylor, 1984).

4.10.2.1 Neuropsychological Interpretation of Children's Measures

Another approach to applying neuropsychological principles in the assessment of children took measures already in use for children (e.g., standardized intelligence tests) and interpreted these measures from a neuropsychological perspective; where existing child measures did not exist, these measures were then developed. L. C. Hartlage and Long (1997) indicated that most practitioners preferred this method (interpreting child-based measures from a neuropsychological perspective) as opposed to using adult measures with child norms. As with adults, this has occurred most frequently with the Wechsler scales. General summary scores of Wechsler scales have been found to be reliable indicators of brain integrity (Black, 1976; Hynd & Willis, 1988). Various subtests of the WISC-R also have been found to correlate with neuropsychological measures (see Batchelor, Sowles, Dean, & Fischer, 1991) and have been used to formulate hypotheses (Kaplan, 1988). Multiple efforts have been made with regard to recategorizing or clustering various subtests to provide for neuropsychological interpretation of the WISC-R. L. C. Hartlage (1982), for example, suggested that the functional integrity of the right and left hemispheres could be estimated by comparing the Similarities and Picture Arrangement subtests (temporal lobe) and the Arithmetic and Block Design subtests (parietal lobe). Bannatyne (1974) proposed four categories of neuropsychological function that could be assessed and interpreted based on combinations of subtests on the WISC-R: verbal comprehension, sequencing, spatial, and acquired knowledge. Kaufman (1979) recategorized the subtests into successive and simultaneous tests, based on Luria's theory.

Concerns with this practice have been evidenced in the literature. Interpretations based on isolated measures of a child's behavior (e.g., a single subtest) have limited reliability and validity (Kamphaus, 1993; Lezak, 1995) and this is often what occurs in this process. Recategorizations of multiple subtests (e.g., Bannatyne, 1974; Kaufman, 1979), appear to have greater reliability, but the validity of these recategorizations continues to be questionable (see Kamphaus, 1993). Further, in many cases there is no attempt to translate the inferences made, using these methods, into effective interventions.

4.10.2.2 Development of New Measures for Children

As opposed to trying to "make do" with existing children's measures, additional measures have been developed with an underlying neuropsychological basis. For example, the Luria–Das model of successive/simultaneous processing (Das, Kirby, & Jarman, 1979) in conjunction with the cerebral lateralization research by Sperry (1968, 1974), Kinsbourne (1975), and others, served as the basis for the development of the Kaufman Assessment Battery for Children (KABC; Kaufman & Kaufman, 1983a). As such, the design of the KABC is compatible with current neuropsychological models of higher order cognitive function (Reynolds & Kamphaus, 1997). Unlike the Wechsler scales, where mode of presentation determines the scale with which a task is associated, on the KABC the cognitive processing demands of the task (e.g., simultaneous or sequential) determine the scale with which it is associated (Kaufman & Kaufman, 1983b). Further, rather than conceptualizing lateralization based on content or method of presentation, the lateralization component of the KABC is based on the way in which the information is processed or manipulated. Within each scale, there is a variation of mode of presentation and response that allows for further evaluation of complex functional systems (Reynolds & Kamphaus, 1997). KABC interpretation is intended to identify cognitive neuropsychological strengths of the child, and the related instructional methods and learning activities that will exploit these strengths and circumvent deficit areas. Research on the effectiveness of this model for intervention is, however, limited.

Evaluation of the KABC with regard to its relevance to Luria's approach and to child neuropsychology has been positive (e.g., Donders, 1992; Majovski, 1984; Snyder, Leark, Golden, Grove, & Allison, 1983). It has been suggested that the KABC is a good complement to other neuropsychological tests. Specifically with regard to the use of the KABC as a component of a neuropsychological battery, it has been shown to provide useful information in the differential diagnosis of learning disability subtypes (e.g., Hooper & Hynd, 1985; Telzrow, Century, Harris, & Redmond, 1985) and right hemisphere dysfunction, which is consistent with physical evidence (Morris & Bigler, 1985; Shapiro & Dotan, 1985). Similar positive results were found in the comparison of dichotic listening performance and KABC results (Dietzen, 1986). Thus, the KABC has been shown to be sensitive to traumatic brain injury to specific cortical regions (Donders, 1992). Research also indicated that the pathognomonic and intellect scales of the Luria Nebraska Neuropsychological Battery-Children's Revision were closely related to performance on the global scales of the KABC (Leark, Snyder, Grove, & Golden, 1983). Research results overall tend to support the use of the KABC in neuropsychological assessment, and subtests of the KABC are frequently used in eclectic batteries (e.g., Nussbaum et al., 1988; Branch, Cohen, & Hynd, 1995).

The KABC may well be the test of choice for children under age five (Reynolds et al., 1997); the use of sample and teaching items adds to the likelihood that a neurological substrate or functional system is being assessed as opposed to language, experience, or culture (Reynolds & Kamphaus, 1997). The KABC has strong validity and reliability (Kamphaus, 1993), is sensitive to developmental changes in information processing/functional organization (Reynolds & Kamphaus, 1997), and is considered an appropriate instrument for use with US ethnic minorities (e.g., Fan, Willson, & Reynolds, 1995; Kamphaus & Reynolds, 1987). While further research with the KABC in conjunction with neuropsychological assessment is needed, available research supports the potential for the KABC to be a useful tool for child neuropsychologists with results providing implications for the habilitation of learning problems (Reynolds & Kamphaus, 1997).

4.10.2.3 Current and Future Trends

The development of new measures, specifically designed and normed for children may not only reflect current interest areas in children's learning and behavior, but may in many ways dictate the future directions of neuropsychological assessment of children. In particular, since the late 1980s a number of measures have been developed which are specific to memory and attention. At the same time, there is also an increase in the use of technology, with or without the inclusion of electrophysiological or imaging methods, which is evident in the research literature and clinical practice.

4.10.2.3.1 Memory

Nearly every disorder that involves the CNS and higher cognitive functions includes some form of memory complaint; memory is incorporated in almost all daily activities (Reynolds & Bigler, 1997a). Research across neurological disorders points to the importance of memory in evaluating brain integrity (Reynolds & Bigler, 1997a); 80% of a sample of clinicians who performed testing noted memory as important (Snyderman & Rothman, 1987). Standard psychoeducational batteries used with children tend to focus solely on cognitive ability as defined by IQ, achievement, and behavioral status. In the area of learning disabilities, there has been recent interest in examining the underlying psychological processes, and particularly learning and memory (Zurcher, 1995). Research in the area of memory and the development of new measures to assess memory functions may lead to further interest in the learning process itself (Reynolds, 1992). It has been argued, additionally, that the assessment of learning and memory would provide useful information for instructional planning (Wasserman, 1995).

Historically, assessment of memory in children relied on the use of subtests from various tests including the KABC, the WISC-III and its earlier versions, and so on (e.g., Nussbaum et al., 1988; Branch et al., 1995). All too frequently, inferences regarding verbal memory in particular relied on the Digit Span subtest of the Wechsler scales. Multiple concerns about relying on Digit Span can be found in the research literature (e.g., Reynolds, 1997a; Talley, 1986). Recent research in the area of memory has suggested that the traditional combining of forward and backward digits may be inappropriate and that these tasks represent quite different cognitive demands (Ramsey & Reynolds, 1995; Reynolds, 1997a) with distinct neuropsychological substrates. Initial findings suggest, for example, that forward memory span may be more directly impacted by attention while backward memory span may be more a reflection of general intelligence. Additional investigation into the distinction between forward and backward memory span, as well as into other areas of memory continues to be needed. Due to the increased interest in this area, children's norms for measures used in the assessment of memory in adults have been developed (e.g., Delis, Kramer, Kaplan, & Ober, 1994). In addition, three comprehensive measures for the assessment of memory/learning have been developed specifically for children and adolescents since the mid-1980s. The development of these measures has in many ways been due to the perceived inappropriateness of adult measures of memory for use with children and the inability to relate results from adult measures to the contexts (e.g., school) in which children function.

The first of the measures developed for the assessment of memory in children, the Wide Range Assessment of Memory and Learning (WRAML; Sheslow & Adams, 1990), consists of 12 subtests which yield verbal memory and visual memory scores, with normative data for children ages 5–17 years. Delayed recall trials can be given for four of the subtests. Initial factor analysis of the WRAML corroborated the two-factor structure (Haut, Haut, Callahan, & Franzen, 1992); however, with at-risk children and a clinical population, three factors were extracted (Aylward, Gioia, Verhulst, & Bell, 1995; Phelps, 1995). Some concern has been voiced with regard to the multiple items/tasks that may tap attention as opposed to memory and the absence of consideration of attention/concentration (Haut et al., 1992). Further, evaluation of the WRAML for children with, compared with those without, ADHD or learning disabilities indicated that the WRAML provided little additional information for discriminating between clinical groups (Phelps, 1996).

The Test of Memory and Learning (TOMAL; Reynolds & Bigler, 1994) consists of 10 core subtests (five verbal and five nonverbal) yielding separate verbal memory and nonverbal memory scale scores as well as a composite memory score. A delayed recall procedure can be implemented to provide a delayed recall index. Additional supplemental indices (e.g., sequential recall, free recall, attention/concentration, and learning) can also be computed. Using a variety of factor analytic methods, Reynolds and Bigler (1996) examined the latent structure of the TOMAL. Factor analytic study of the TOMAL indicated that the factor solutions obtained were highly stable across all age groups. Notably, none of the solutions obtained matched the verbal–nonverbal dichotomy usually considered and represented by the two scales of the TOMAL. Instead, what emerged were components representing various levels of complexity in memory tasks and processing demands that cut across modalities. Alternative methods of interpretation based on the factor analytic results are available (see Reynolds & Bigler, 1996). The TOMAL does provide separate scores for forward and backward recall, in contrast to many scales that combine these inappropriately. Unlike most neuropsychological measures (Reynolds, 1997b), the TOMAL included studies of ethnic and gender bias during standardization; items showing cultural biases were eliminated.

Most recently, the Children's Memory Scale (CMS; Cohen, 1997) was developed with linkages to the WISC-III built in to the standardization process. The composition of the CMS was based on extensive clinical practice with initial tasks and items, field trials of the measures, and feedback from clinicians involved in the field trials. The CMS consists of six core subtests representing verbal memory, attention/concentration, and visual/nonverbal memory as well as three supplemental subtests. The CMS provides for evaluation of immediate recall as well as delayed recall of the verbal and nonverbal memory areas. For scoring purposes, seven index scores can be calculated to examine differences between immediate/delayed verbal/visual memory, learning, recognition, and attention/concentration. Factor analytic studies of the standardization sample were conducted and four models evaluated to determine the "best fit." Results indicated that the three-factor solution (attention/concentration, verbal memory, visual memory) was the most consistent (Cohen, 1997).

4.10.2.3.2 Attention

It has been argued that the most frequent symptoms associated with childhood neuropsychological disorder include attention/concentration, self-regulation and emotional/behavioral problems (Nussbaum & Bigler, 1990). Further, it is the neural traces left by attention that are likely the root of memory. It is not surprising that there is increased interest in the measurement of attentional processes or that these are seen as an important component of the assessment process. The assessment of attention, more so than of other domains, has moved to computerized approaches. The most comprehensive battery of computerized measures is the Gordon Diagnostic System (GDS; Gordon, 1983). This is a microcomputer-based assessment that includes 11 tasks specific to attention and self-regulation. Since the development of the GDS, a number of other computer-based measures of attention and impulsivity have been developed and marketed. These programs tend to vary with regard to the actual paradigm used; there are variations in the modality employed, the type of stimuli, and the nature of the task (Halperin, 1991).

Continuous performance tests (CPTs), for example, may require a response only when a specified target stimulus is presented (if X) or only when the target stimulus follows another specified stimulus (if AX) and so on. A further variation of this is a similar task where the required "response" to the presentation of the target stimuli is, however, to inhibit responding (Conners, 1995). The stimuli may be presented in a visual or auditory format, or in a combination format requiring a modality shift. Also, depending on the program used, the scores may be limited to correct responses, commission errors, and omission errors, or may include reaction time information.

Through the use of computerized measures of attention, knowledge specific to the developmental nature of attentional processes has been gleaned (Mitchell, Chavez, Baker, Guzman, & Azen, 1990). Research has demonstrated the usefulness of computerized measures of attention and self-regulation for monitoring the effects of medical management (e.g., Barkley, DuPaul, & McMurray, 1991; Barkley, Fischer, Newby, & Breen, 1988; Hall & Kataria, 1992). It was anticipated that computerized assessment of attention would provide more objective data in the assessment process for ADHD as well as providing information specific to attentional deficits associated with traumatic brain injury or other neurological disorders (Timmermans & Christensen, 1991). The results of studies with various paradigms for CPTs are equivocal with regard to discriminant validity specific to ADHD (e.g., Barkley et al., 1991; Wherry et al., 1993) as well as concerning the extent to which results are consistent with teacher perceptions (Barkley, 1991, 1994). Interpretation of these measures is limited by the availability of comprehensive research with any one software program. The extent to which cultural differences, gender differences, cognitive ability, order effects, and so on impact on CPT performance is unknown. Further, the extent to which the particular paradigms used provide predictive information that may be helpful in intervention planning has not been studied.

4.10.2.3.3 Computer-administered assessment

Measures of attention are not the only computer-based assessment tools. A computerized neuropsychological test battery for adults has been developed (Powell et al., 1993), computer-administered interviews and self-reports are available, and specific neuropsychological tests or their analogs can be administered via computer (e.g., Burin, Prieto, & Delgado, 1995; Heaton, 1981). Computerized assessment of children's reading skills has been investigated with indications of high coefficients of equivalence with traditional assessment (Evans, Tannehill, & Martin, 1995). With advances in microcomputers, the use of computerized assessment will likely increase in the near future.

The use of computers and technology in assessment has a number of advantages and clearly allows for the development of an increasing variety of tasks without excessive and cumbersome testing materials; computerized assessment may be less time-consuming and, as such, cost- and time-effective. Further, the speed or measure of time to task completion is considered one of the most sensitive indices in neuropsychological assessment and computer programs can provide increased accuracy in the measurement of speed of processing (Kane & Kay, 1997). Kane and Kay (1997) point out a number of additional advantages to the use of computers in the assessment process, including presentation of items at a fixed rate (computer-paced) as well as providing for accurate measure of time to completion (child-paced). Computers can also be used to generate multiple forms of a test, thus providing baseline data as well as a means of monitoring change over time. With computerized assessment, standard/uniform administration is ensured and results are free of potential bias. Computers further facilitate the production of relevant test statistics (Kane & Kay, 1997).

There are however, multiple concerns and disadvantages with "diagnosis by computer." Predominant among these is the loss of information from not being able to observe the process and strategy used by the individual in reaching the solution (Powell, 1997). First (1994) concluded that computerized assessment processes were advantageous, but cautioned that clinicians must continue to be a strong component in the diagnostic process in order to provide for diagnostic validity. Computers cannot replace the information gained from interaction and clinical observation of process nor can a computer draw conclusions regarding level of attention, motivation, fatigue, and so on that may be cues to discontinue testing for a brief period. Computers also cannot provide the child with prompts and encouragement as needed to maintain performance over time (Kane & Kay, 1997). At the extreme, there is the potential for computers to be used as a substitute for a complete evaluation and this is of concern (Kane & Kay, 1997). First (1994) asserted that clinicians needed to be well advised of the limitations as well as the strengths of computerized assessment procedures. As the number of computer-driven assessments increases, there will need to be an analogous increase in the research field comparing the various programs and their psychometric properties with each other and with more traditional methods of assessments. At the time of writing, in the late 1990s, many computerized assessment methods fail to meet established testing standards (Kane & Kay, 1997).

4.10.2.3.4 Integration of neuroimaging and electrophysiology

With advances in neuroscience, clinical and research protocols may more frequently include neuroradiological methods in conjunction with neuropsychological techniques in order to enhance understanding of childhood disorders. This type of "partnership" is already occurring in a number of research areas (e.g., Bigler, 1991; Denckla, LeMay, & Chapman, 1985; Duffy, Denckla, McAnulty, & Holmes, 1988; Hynd, Marshall, & Semrud-Clikeman, 1991). The integration of information from neuroradiology with neuropsychological assessment has already established relationships for specific lesions and associated behaviors and is beginning to establish a better understanding of the relationship between myelination differences and white/gray matter ratios (e.g., Harbord et al., 1990; Jernigan & Tallal, 1990; Turkheimer, Yeo, Jones, & Bigler, 1990). The availability of imaging using ultrasound has added to the knowledge of relationships between gross abnormalities evident *in vitro* and later negative outcomes (e.g., Beverley, Smith, Beesley, Jones, & Rhodes, 1990; Iivaneihan, Launes, Pihko, Nikkinen, & Lindroth, 1990). Measurement issues in imaging, such as differences in resolution from one magnetic resonance image to another, continue to be problems in this area, but will hopefully be resolved in the future. While in the past routine EEG of children did not offer much utility in the evaluation of learning or behavior problems, the development of computer-assisted analysis has improved the interpretability of electrophysiological measures (Duffy & McAnulty, 1990).

Computerized measures have been developed to examine more closely the speed of information processing, through reaction time paradigms that have included linguistic (e.g., Lovrich, Cheng, & Velting, 1996) as well as visual stimuli (Novak, Solanto, & Abikoff, 1995), in conjunction with electrophysiological measures.

This integration of methods across neuroscience and neuropsychology is providing further evidence concerning brain–behavior relationships and adding to the knowledge base related to neurodevelopmental processes in children and adolescents. Functional imaging and other imaging quantification methods hold promise for furthering the future understanding of neuropsychological performance (Bigler, 1996). Similarly, it has also been argued that a comprehensive and integrative assessment process, that involves both the neurologist and neuropsychologist with the tools and expertise of both disciplines, may enhance the value and role of neuropsychological assessment (Batchelor, 1996a, 1996b).

4.10.2.3.5 Integration of cognitive and developmental psychology

Neuropsychological assessment of children is being influenced more and more by developmental and cognitive psychology. This is most apparent in the areas of language, attentional processes, and executive functions (Williams & Boll, 1997). Integration across fields has been suggested specifically with regard to metacognition (from cognitive psychology) and executive function (Torgesen, 1994). The domain of "executive function" may incorporate a variety of constructs (e.g., attention, self-regulation, working memory) but the "executive" processes generally focus more on effortful and flexible organization, strategic planning, and proactive reasoning (Denckla, 1994). Denckla further asserted that executive function cannot be dealt with as a "composite" of scores on various measures, but must be fractionated. The measurement of executive function in children is exceptionally difficult due to the ongoing development and maturation of the frontal lobes through adolescence. Factor analytic study of executive function tasks (Welsh et al., 1991) yielded factors that appeared to be divided according to developmentally related constructs as opposed to theoretical ones (Denckla, 1994). The majority of measures for executive function which are used with children are downward extensions of adult measures and many lack sufficient normative data and psychometric study. In addition, the emphasis on the use of novel tasks in the assessment of executive function places significant limitations on the evaluation of interventions in the area of executive processes. Torgesen (1994) argued that current measures of executive function, with the presumed assumption for a need for novelty, evidence a lack of cross-theoretical integration between neuropsychology and the information-processing paradigms. He further stated that there is a need to include assessment of tasks that are ecologically based and require executive function, in order to enhance the evaluation of treatment programs designed to remediate executive processes. Certainly, the production of child-centered, developmentally sensitive measures of executive processing, that are more directly linked to real-life activities thus facilitating the development of interventions, and that have sufficient flexibility to allow for pre- and postevaluation, is needed. Overall, integration of neuropsychological assessment and models of cognitive development may lead not only to a better understanding of deficit processes but also to better remediation/habilitation programs (Williams & Boll, 1997).

4.10.2.4 Measurement Issues

Although research methods and statistical tools have greatly improved since the early 1970s, clinical child neuropsychology has been criticized for its failure to attend to principles of research and to incorporate psychometric advances (Cicchetti, 1994; Parsons, & Prigatano, 1978; Reschly & Gresham, 1989; Ris & Noll, 1994; Sandoval, 1981; Willson & Reynolds, 1982). Problems with statistical methods and design in clinical neuropsychology have been frequently noted (e.g., Adams, 1985; Dean, 1985; Reynolds, 1986a, 1986b, 1997b).

One major concern relates to the extent and nature of normative data for many measures used in the neuropsychological assessment of children. Although clinical insight may be gained by observation of test performance, sound normative data provides a backdrop against which to evaluate that insight (Reynolds, 1997b). The systematic development and presentation of normative data across the lifespan for many tools used in neuropsychological assessment have received far too little attention to date (Reynolds, 1986b) and greater attention in this area is needed. Good normative data require extensive systematic and stratified sampling of a population in order to obtain a reliable standard against which to judge the performance of others. The provision of adequate normative data has multiple benefits for the field of neuropsychology, including improved communication among clinicians and researchers, increased accuracy in diagnosis, and facilitation of training for new members to the discipline. In addition, good normative data provide the opportunity to deflate and expose a variety of clinical myths (Reynolds, 1986b).

Most of what is known about the measures used is specific to the performance of those with identified brain injury/insult as opposed to typically developing individuals. Normative data that are available in the literature are often based on small samples, may have been collected in a single geographical region, and do not reflect the ethnic diversity, socioeconomic levels, or gender composition of the general population. In many cases, the sample is predominantly male and Caucasian, yet research suggests that gender and cultural differences may also contribute to variations in brain organization (e.g., McGlone & Davidson, 1973).

The lack of sufficiently large, stratified samples in the development and standardization of neuropsychological assessment inhibits the understanding of demographic influences (Reynolds, 1997b) and thus complicates test interpretation (Dean, 1985). That cultural differences exist on standardized measures is well documented. Mostly, the use of neuropsychological measures with Hispanic populations has been studied (e.g., Ardila & Roselli, 1994; Ardila, Roselli, & Putente, 1994; Arnold, Montgomery, Castenada, & Langoria, 1994), but overall research on the effects of cultural differences (e.g., differences in the value of speed of responding) is sparse. Differences between ethnic groups have also been examined with respect to specific measures of memory (e.g., Mayfield & Reynolds, 1997). However, for most neuropsychological measures there has been no study of ethnic and gender differences; cultural/ethnic differences are infrequently accounted for in the collection of normative data and therefore cannot be used in the interpretation process.

All too frequently, neuropsychologists rely on the "clinical" nature of the test and overlook the psychometric concepts of reliability and validity. The need for the establishment of reliability of neuropsychological measures has been cited in the literature (e.g., Parsons & Prigatano, 1978, Reynolds, 1982); reliability information on neuropsychological measures is not routinely reported in research studies and is frequently not included in the test manuals (Reynolds, 1997b). Reliability of test scores is important as it relates to the amount of variance that is "real," systematic, and related to true differences between individuals. Therefore, it is important to determine the reliability of neuropsychological measures for purposes of individual diagnosis as well as for research, in that reliability influences the likelihood that any experimental or treatment effects will be detected (Reynolds, 1986b). Reliability is also the foundation on which validity is built.

Related to issues of reliability and validity, the method of scaling/measurement used with any test or measure is "crucial" (Reynolds, 1997b, p. 189). Scaling across neuropsychological measures, however, is inconsistent. Frequently what are obtained are raw scores for number correct, time for completion, or number of errors. This results in the need to use score transformations, based on insufficient normative data, in order to make any kind of meaningful comparison. Alternatively, clinicians may use inappropriate scales such as age or grade equivalents in an attempt to give meaning to raw data (Reynolds, 1997b). Grade equivalents, in particular, are inappropriate due to the extent of extrapolation that is used in their derivation as well as faulty assumptions that are made with regard to learning and growth over time (e.g., from lower to upper grades, across subject areas, and throughout the calendar year). Further, grade equivalents exaggerate small differences in performance between individuals and for a single individual across tests (Reynolds, 1986b). It is, therefore, imperative that standard score conversions, based on adequate normative data, be provided for measures used in neuropsychological assessment.

It has been asserted that by age 10 or 12 children perform at adult levels in some areas, and for many older neuropsychological measures most of the normative sampling, in addition to using small numbers, often stopped at age 12. This is despite the fact that many researchers have suggested that neurodevelopment continues through at least age 14 (Boll, 1974) and possibly through age 16 (Golden, 1981). This further limitation in the provision of normative data impedes the interpretation process for adolescents, bolsters the assumption that adolescents should function as adults, and promotes the use of downward extensions of adult measures that often are not appropriate. Neuropsychological function is developmental, and distinct age-related norms are required. It has also been recommended that item response theory (IRT) be used to ensure that neuropsychological measures include an adequate range of difficulty levels, thus ensuring coverage of developmental levels (Morris, 1994). Most existing neuropsychological measures, however, have not been subjected to this type of analysis.

The standardization of administration procedures is also an area of concern. Reynolds (1986b) commented on the availability of at least four versions of Halstead's category test, three of which were somewhat similar and the fourth with significant differences in terms of administration. Despite these differences, however, the same normative data are used. Similarly, administration of the Wisconsin Card Sorting Test (Heaton, 1981) can be done traditionally or via computer, yet there is a single normative data set to be used for scoring and interpretation. Differences in administration impact on the validity and reliability of the measure and normative data, including validity studies, for each variation of administration (unless controlled in the standardization process) are necessary.

Sensitivity, specificity, and diagnostic accuracy need to be further researched as well. Sensitivity is the extent to which a given test accurately predicts brain impairment and is often gauged by statistical power (Pedhazur, 1973). Sensitivity is dependent on validity. No single neuropsychological measure demonstrates high sensitivity (Boll, 1978); combined scores from a given battery may be more successful (e.g., Selz & Reitan, 1979a). In contrast, specificity is dependent on the nature of the behavioral, cognitive, and emotional functions of the task (Batchelor, 1996b). The extent of specificity can only be determined by comparing clinical groups to each other as opposed to focusing on differences between a specific clinical group and the normal population. Cross-clinical group comparisons are frequently not done however. When research is based on comparisons across clinical groups, the results are generally inconclusive (Koriath, Gualtieri, van Bourgondien, Quade, & Werry, 1985).

In comparing clinical groups, it is important to control for comorbidity and family history (Seidman et al., 1995) as well as to differentiate between subtypes of a given disorder when these have been identified (e.g., Halperin, 1991). For many disorders, subtypes have been validated, yet frequently research studies with clinical groups rely on the more global rubric. With regard to learning disabilities, Rourke (1994) asserted that this "lumping" together may lead to gross misunderstanding, if not to conflicting results across studies. For example, the need to develop and incorporate typologies/subtypes for homogeneous grouping of children with dyslexia, for the purposes of developing appropriate intervention as well as for research purposes, has been recognized for some time, yet much of the educational and psychological literature and practices relating to dyslexia continue to address heterogeneous groups of children without regard for subtype (Reynolds, 1986b). Differing typologies and comorbidity have rarely been considered in the extant literature on many neuropsychological measures and likely contribute to the conflicting results of differing studies. Further, the constructs being measured by given tasks may be influenced by gender, premorbid status, the task itself, neuropsychological functions, and so on, making a high level of specificity difficult to attain (Batchelor, 1996b). Batchelor (1996b) suggested that many neuropsychologists compromise between sensitivity and specificity through the selection, administration, and interpretations of neuropsychological measures that are needed to effect such a balance.

Often, in an attempt to provide accurate differential diagnosis, a large set of behaviors is typically assessed. Researchers then use multivariate classification procedures for determination of group information or to determine the effectiveness of specific measures in the diagnostic process. The sample sizes in many of the studies, however, are too small for multivariate analysis, given the large number of variables involved. As a result, in the absence of cross-validation, many diagnoses or classifications may be due to random relationships (Willson & Reynolds, 1982). Problems with the lack of consistency in the diagnosis/classification of disorders also impede the research process and ultimately, clinical practice (Hooper & Tramontana, 1997).

4.10.2.5 Approaches to Test Selection with Children

In addition to selecting tests based on psychometric properties, it has been suggested that child neuropsychologists should select measures that vary along a continuum of difficulty, include both rote and novel tasks, and vary the tasks with regard to processing and response requirements within modalities (Rourke, 1994). Many neuropsychologists continue to include observation and informal assessment; others have adopted more actuarial approaches; many use a combination of observation, informal assessment, and actuarial approaches (Reynolds, 1997b), with a focus on direct appraisal of functions and abilities in order to obtain detailed information on the behavioral effects of brain impairment (Tramontana, 1983). It has been argued that the use of actuarial methods that rely on standardized measures to obtain information may not, however, be useful in intervention planning (D'Amato, 1990).

In addition to quantitative measures, neuropsychological assessment may incorporate not only Luria's theory but also his qualitative assessment model (Luria, 1966, 1970). Luria described assessment that was flexible and varied from individual to individual depending on the functional system that was of concern (Teeter, 1986). Although more dependent on clinician interpretation, qualitative methods can add to information related to the process of learning and may be better suited to the development of intervention/treatment plans (D'Amato et al., in press). In the incorporation of qualitative tasks, child neuropsychologists make use of work samples, informal tasks, criterion-referenced measures and clinical observations of interactions throughout the assessment process (D'Amato et al., 1997). Qualitative procedures can also be used to complete a task analysis and determine specifically which components of a more complex task are problematic for the child (Taylor, 1988). Others may use standardized measures but administer them in other than standardized fashion (Kaplan, 1988). Modifications of tasks presented (e.g., provision of cues, adjustment of rate, changing modality of presentation or response, adjustment of task complexity) can provide insight into processing differences (Clark & Hostettler, 1995; Harrington, 1990; Ylvisaker et al., 1990) and have been recommended for use in the evaluation of children who are culturally or linguistically diverse (Gonzalez, Brusca-Vega, & Yawkey, 1997). Unfortunately, tests administered with these types of modifications are no longer consistent with standardization procedures, and clinicians need to exercise caution in the interpretation of brain–behavior relations based on qualitative data (D'Amato et al., in press). A strictly qualitative approach using experimental/ad hoc measures and nonquantitative/ nonstandardized interpretation of standardized measures may provide additional information, but does not allow for verification of diagnostic accuracy, is not easily replicated, and does not allow for formal evaluation of treatment methods (Rourke, 1994). In practice, most clinicians prefer a combination of quantitative and qualitative measures (Rourke, 1994).

Test selection in the neuropsychological assessment of children and young people varies considerably from clinician to clinician due to differences in philosophy and theoretical foundations. Evaluation may take the form of various published battery approaches (e.g., Golden, 1997; Reitan, 1974; Selz, 1981) or may use a more eclectic approach (e.g., Benton, Hamsher, Varney, & Spreen, 1983; Gaddes, 1980; Hynd & Cohen, 1983; Knights & Norwood, 1979; Obrzut, 1981; Obrzut & Hynd, 1986; Rourke, Bakker, Fisk, & Strang, 1983; Rutter, 1983; Spreen & Gaddes, 1979; Teeter, 1986; Tramontana & Hooper, 1987). Generally, however, the approaches can be categorized as nomothetic, idiographic, or a combination of these two approaches. Additional variation within categories, however, is evident in the extent to which clinicians rely on quantitative, qualitative, or both types of information in the process.

4.10.2.5.1 Nomothetic approaches

The fixed/standardized battery or nomothetic approach uses the same assessment protocol for all children being assessed. An example of the nomothetic approach would be the administration of a published neuropsychological battery, usually in conjunction with IQ and achievement tests. It may also be a predetermined set grouping of selected tests that remains constant across children evaluated, regardless of the referral problem (Sweet, Moberg, & Westergaard, 1996). These tend to be more actuarial in nature (Lezak, 1995) and often rely on cut-off scores, pathognomonic signs, or a combination, for determination of the presence of brain damage. The choice of a fixed battery approach is generally related to an orientation and preference consistent with standardized procedures, objective methods, and psychometric development. It may also reflect a preference for "blind" assessment such that the referral problem does not dictate the measures used (Goldstein, 1997). This approach has the advantage of covering a breadth/depth of functions, provides for extensive databases, and facilitates the collection of data for clinical interpretation of large numbers of clinical groups. Standardized/nomothetic batteries, however, often do not take into consideration education, age, and experiential variables, and may or may not specifically address the referral question. Further, diagnosis with a nomothetic approach may be driven by the base rates of the clinical problems in a particular setting, due to sampling bias, and therefore may not be useful for detecting disorders in other population samples (Tramontana & Hooper, 1987). Use of a standardized battery/nomothetic approach appears to be declining in the general area of clinical neuropsychology (Sweet et al., 1996); however it may be the preferred method if litigation is a potential issue (Reitan & Wolfson, 1985).

The published neuropsychological batteries most frequently used with school-aged children are the Luria Nebraska Neuropsychological Battery-Children's Revision (LNNB-CR; Golden, 1984), the Halstead–Reitan Neuropsychology Battery (HRNB; Reitan & Davison, 1974) and the Reitan Indiana Neuropsychological Test Battery for Children (RINB; Reitan, 1969). All of these batteries require extensive training for appropriate administration and interpretation of results. The neuropsychological battery is often supplemented with a traditional test of cognitive ability as well as achievement testing.

The HRNB and RINB are considered to be the most widely used in clinical practice (Howieson & Lezak, 1992; Nussbaum & Bigler, 1997). Both of these use a multiple inferential approach to interpretation, including level of performance, pathognomonic signs, patterns of performance, and right–left differences (Reitan, 1986, 1987). The batteries contain numerous measures that are considered necessary for understanding brain–behavior relationships in children and adolescents. Descriptions of these measures are provided in Tables 1 and 2. Both the HRNB and the RINB can be used in clinical practice for the assessment of a child with identified brain damage as well as with those children where specific brain damage has not been documented through neuroradiological methods (Nussbaum & Bigler, 1997).

Strong correlations have been found between the Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler, 1974) and the RINB and HRNB (Klesges, 1983) suggesting the ability of the latter tests to predict neuropsychological dysfunction. A number of factor analytic studies have been completed comparing results from the WISC-R and the Reitan batteries (e.g., Batchelor et al., 1991; D'Amato, Gray, & Dean, 1988; Snow & Hynd, 1985a); these consistently suggest that most of the variance is due to factors of language, academic achievement, and visual spatial skills. With the addition of other measures, up to eight factors were found (D'Amato et al., 1988; Batchelor et al., 1991). Although factor analytic research has demonstrated a good deal of common information when the WISCR and HRNB were both given, it has also been determined that the HRNB offers unique information (Klonoff & Low, 1974) and the addition of the HRNB to the typical psychoeducational battery has been found to increase the extent to which variability in school achievement can be accounted for (Strom, Gray, Dean, & Fischer, 1987). Research regarding the efficacy of the HRNB in the differential diagnosis of children with learning problems is equivocal (Arffa, Fitzhugh-Bell, & Black, 1989; Batchelor, Kixmiller, & Dean, 1990; Selz & Reitan, 1979a, 1979b). Factor analytic research with the RINB has been less conclusive (Crockett, Klonoff, & Bjerring, 1969; Foxcroft, 1989; Teeter, 1986). The RINB has been found to be sensitive to mild levels of traumatic brain injury within four months of injury in the absence of obvious lags in academic achievement (Gulbrandson, 1984). The HRNB and RINB are both downward extensions of the adult version with some modifications for children (Teeter, 1986) and do not fully reflect the developmental continuum of childhood and youth (Cohen et al., 1992).

The LNNB-CR was developed on the basis of the neurodevelopmental stages of the child (Golden, 1981, 1997) and was revised four times in the process (Plaisted, Gustavson, Wilkening, & Golden, 1983). It is designed for children ages 8–12 years and in addition to IQ and achievement provides information specific to motor, rhythm, tactile, visual, receptive speech, expressive language, and memory functions. A description of the LNNB-CR is provided in Table 3. The development of the LNNB-3 represents an extensive revision and major expansion of the LNNB-CR and the adult version. It includes tasks from the previous two measures, but also includes additional tasks, with a total of 27 domains being evaluated. With this major revision, both lower level and more complex tasks and items have been added. The LNNB-3 is intended for use with individuals from age five through adulthood. Interpretation of the LNNB-CR and LNNB-3 focuses predominantly on scale patterns and intrascale (intraindividual) differences, as opposed to levels of performance or pathognomonic signs.

Due to its recent development, there is little research available on the LNNB-3 and most is specific to adults (e.g., Crum, Bradley, Teichner, & Golden, 1997; Crum, Golden, Bradley, & Teichner, 1997). Extensive research has, however been completed with the LNNB-CR. Factor analytic studies (e.g., Karras, Newton, Franzen, & Golden, 1987; Pfeiffer, Naglieri, & Tingstrom, 1987; Sweet, Carr, Rossini, & Kasper, 1986) have resulted in varying factor structures. It has been determined consistently that the LNNB-CR offers unique information not otherwise obtained in psychoeducational assessment, with particular sensitivity to deficits in language, writing, reading, and rhythm (Geary & Gilger, 1984). The pathognomonic scale of the LNNB-CR has been found to account for increased variance, independently of the WISC-R, and to be a better predictor of academic achievement in spelling and reading (McBurnett, Hynd, Lahey, & Town, 1988). It was also found that the LNNB-CR had greater shared variance than the WISC-R with measures of achievement (Hale & Foltz, 1982). The LNNB-CR has been found to be more sensitive to improvement in functioning following medical intervention (e.g., shunt placement) than either cognitive or achievement measures (Torkelson, Liebrook, Gustavson, & Sundell, 1985), as well as supporting differential diagnosis (Carr, Sweet & Rossini, 1986) and the understanding of academic deficits in children with emotional/behavioral problems (Tramontana, Hooper, Curley, & Nardolillo, 1990). The utility of the LNNB-CR in the differentiation of learning disability as opposed to other forms of brain damage, however, has been questioned (e.g., Morgan & Brown, 1988; Oehler-Stinnett,

Table 1 Halstead–Reitan Neuropsychological Battery for Children (ages 9–14 years).

Subtest	*Description*	*Function(s) assessed*
Category test	Requires individual to select colors or numbers corresponding to some abstract problem-solving criteria. Immediate feedback is provided for both correct and incorrect responses.	This task assesses general abstraction and concept formation as well as general neuropsychological functioning (Reitan & Wolfson, 1985, 1988).
Tactual performance test	The individual is blindfolded and required to place blocks in slots on a form board using the dominant hand, the nondominant hand, and both hands together. The individual is then asked to draw a diagram of the board with the blocks in their proper spaces.	This task measures tactual discrimination, sensory recognition, and spatial memory. The drawing component is a measure of incidental learning/memory (Reitan & Wolfson, 1988; Selz, 1981).
Speech sounds perception	A taperecorded voice presents a sequence of 60 spoken nonsense words from which the individual must select the correct word each time from three written choices.	This task measures alertness, attention/concentration, and verbal ability (Reitan & Wolfson, 1988)
Seashore rhythm test	The individual is required to differentiate between 30 pairs of rhythmic patterns which are sometimes the same and sometimes different.	This test is thought to be an indicator of generalized cerebral function as well as a measure of alertness and attention/concentration. (Reitan & Wolfson, 1988)
Trail making test	This test uses two tracking tasks, one with numbers (A) and one with letters and numbers (B). First, the individual must connect numbered circles in order; then, the individual must connect circles in sequence, alternating numbers and letters.	The test is believed to measure conceptual flexibility, symbolic recognition, and visual tracking under time constraints (Selz, 1981). It is also used as a measure of overall functioning (Reitan & Wolfson, 1985, 1988).
Finger oscillation test	This test requires the individual to depress a lever as quickly as possible with the index finger of each hand.	This measures motor speed and manual dexterity (Selz, 1981) and lateral dominance (Reitan & Wolfson, 1988.)
Aphasia screening test	This test includes enunciation of spoken language (repeating), naming, reading, writing, spelling, and arithmetic. It also includes copying of a square, circle, and Greek cross.	It is a measure of verbal ability. The drawings are indicative of the verbal-to-motor process (Reitan & Wolfson, 1988).
Sensory perceptual examination		All measure receptive sensory function (Reitan & Wolfson, 1985, 1988).
Tactile perception	The individual is asked to report whether right hand, left hand, right side of face, or left side of face is touched; touches are done unilaterally and bilaterally.	
Auditory perception	Examiner lightly rubs fingers together at the individual's right, left or both ears and the individual is asked to localize the sound produced.	
Visual perception	The individual is asked to report peripheral, unilateral and bilateral single movements produced by the examiner, to assess all four quadrants of the visual field.	

Table 1 (continued)

Subtest	*Description*	*Function(s) assessed*
Tactile form recognition	The individual must identify a cross, triangle, square or circle when put in the dominant hand behind a board (unseen) and point to that same object with the nondominant hand; the same process is then carried out with the object in the nondominant hand.	This test is believed to measure tactile perception as well as attention (Nussbaum & Bigler, 1997).
Fingertip number writing	This requires the individual to identify numerals written on their fingertips (both hands).	This is a measure of sensory perceptual functioning (Reitan & Wolfson, 1988).
Grip strength test	Using a hand dynamometer, the strength of grip for the dominant and nondominant hand is determined.	This measures motor functioning and lateral dominance (Reitan & Wolfson, 1988)

Stinnett, Wesley, & Anderson, 1988; Snow & Hynd, 1985b; Snow, Hynd, & Hartlage, 1984). Hynd (1992) also questioned the appropriateness of the standardization sample.

More recently, the Neuropsychological Investigation for Children (NEPSY; Korkman, Kirk, & Kemp, 1997) has been developed for young children. Based on Luria's model (1970), the NEPSY consists of 27 subtests that are summarized in test profiles of strengths and weaknesses. Initially developed in Finnish, in its English version the test includes subtests specific to attention and executive functions, and language, sensorimotor, visuospatial and memory/learning functions (Korkman et al., 1997). It is intended for use with children age 3–12 years. Early research on the NEPSY appears positive (e.g., Korkman, 1988; Korkman, & Hakkinen-Rihu, 1994; Korkman, Liikanen, & Fellman, 1996); however, additional research with this measure, particularly in comparison to the KABC for younger children, will be needed following publication.

In addition, a new battery, the Dean–Woodcock Neuropsychological Assessment System (DWNAS: Dean & Woodcock, in press) is in the process of development. Based on the work of Catell and Horn (Horn, 1988, 1991), this battery combines the cognitive battery of the Woodcock–Johnson Psychoeducational Battery-Revised with a newly developed battery of sensorimotor tests, a structured interview, and a mental status exam. The sensory and motor portion is projected to include eight tests of sensory function and nine tests of motor function. Although some of these tests are similar to those on other neuropsychological batteries, standardized administration, objective scoring criteria, and normative data will be provided for all tasks. The structured interview and mental status exam are intended to provide information specific to emotional state, motivation, temperament, and prior medical conditions as well as to premorbid history, age at onset and emotional reaction (coping) that may influence neuropsychological performance (Dean & Woodcock, in press). It is projected that this battery will be available in both English and Spanish, with general as well as focused norms that account for age and education using regression methods. As with the NEPSY, clinical research with the DWNAS will be needed once all components of the system are available.

Nomothetic approaches may also be eclectic and use selected measures to sample behaviors from the differing functional systems. Several examples of eclectic batteries can be found in the research literature (e.g., Nussbaum et al., 1988; Rourke, 1994). Since the combinations of measures vary in an eclectic battery from clinical setting to clinical setting, research regarding the efficacy of any given combination of tasks as compared to other combinations or to the published batteries is not feasible, and factor analytic studies of eclectic batteries are not routinely found in the research literature.

4.10.2.5.2 Idiographic approaches

At the other end of the continuum, an idiographic approach tailors the assessment battery to the referral question and the child's individual performance on initial measures administered (Christensen, 1975; Luria, 1973). This type of approach is intended to isolate neurobehavioral mechanisms that underlie the problem of a particular individual rather than

Table 2 Reitan Indiana Neuropsychological Battery (ages 5–8).

Subtest	*Description*	*Function(s) assessed*
Category Test	Requires the individual to select colors or numbers corresponding to some abstract problem-solving criteria. Immediate feedback is provided. This version has fewer items and only five categories.	This task assesses general abstraction and concept formation as well as general neuropsychological functioning. (Reitan & Wolfson, 1985).
Matching pictures test	The child matches a single picture to the same picture or to a picture from a more general category.	This task assesses abstraction and concept formation (Reitan & Wolfson, 1988).
Color form test	The child must alternately touch shapes and colors.	This task assesses abstraction and concept formation (Reitan & Wolfson, 1988).
Progressive figures test	The child must use the small shape within a large shape to select the outer shape of the next figure in sequence in a timed condition.	This task assesses concept formation (Reitan & Wolfson, 1988). Also involves cognitive flexibility and attention (Nussbaum & Bigler, 1997)
Tactual performance test	The individual is blindfolded and required to place blocks in slots on a form board using the dominant hand, the nondominant hand, and both hands together. The individual is then asked to draw a diagram of the board with the blocks in their proper spaces.	This task measures tactual discrimination, sensory recognition, and spatial memory. The drawing component is a measure of incidental learning (Reitan & Wolfson, 1988; Selz, 1981).
Finger oscillation test	This test requires the individual to depress a lever as quickly as possible with the index finger of each hand.	This measures motor speed and manual dexterity (Selz, 1981) and lateral dominance (Reitan & Wolfson, 1988.)
Fingertip symbol writing	This requires the individual to identify Xs and Os written on their fingertips (both hands).	This is a measure of sensory perceptual functioning and attention (Reitan & Wolfson, 1988).
Marching test	The child is required to touch a sequence of circles as quickly as possible.	This measures motor functioning (Reitan & Wolfson, 1988).
Sensory perceptual examination		All measures are sensitive to receptive sensory function (Reitan & Wolfson, 1985, 1988).
Tactile perception	The individual is asked to report whether right hand, left hand, right side of face, or left side of face is touched; touches are done unilaterally and bilaterally.	
Auditory perception	Examiner lightly rubs fingers together at the individual's right, left or both ears and the individual is asked to localize the sound produced.	
Visual perception	The individual is asked to report peripheral, unilateral and bilateral single movements produced by the examiner, to assess all four quadrants of the visual field.	
Grip strength test	Using a hand dynamometer, the strength of grip for the dominant and nondominant hand is determined.	This measures motor functioning and lateral dominance of the upper body (Reitan & Wolfson, 1988).

Table 2 (continued)

Subtest	*Description*	*Function(s) assessed*
Tactile form recognition	The individual must identify a cross, triangle, square, or circle when put in the dominant hand behind a board (unseen) and point to that same object with the nondominant hand; the same process is then carried out with the object in the nondominant hand.	This test is believed to measure tactile perception as well as attention (Nussbaum & Bigler, 1997).
Aphasia screening test	This test includes enunciation of spoken language, naming, reading, writing, and arithmetic; naming, identifying body parts, left/right, numerals and letters. It also includes drawing a square circle, and Greek cross. It is an abbreviated version of the screening test for older children and adults.	It is a measure of verbal ability. The drawings are indicative of the verbal-to-motor process (Reitan & Wolfson, 1988).
Individual performance		These measure visual perceptual and spatial abilities (Reitan & Wolfson, 1988).
Matching Vs, figures	Child must match figures or Vs.	
Star, concentric squares	Child must copy figures of varying difficulty.	

providing a detailed evaluation of all areas of functioning. With no predetermined uniformity across evaluations and the dependence on the individual's presenting problems, this approach requires substantial clinical knowledge to determine the components of the battery in order to meet this goal. Due to the limited data on neuropsychological functions and organization of behavior in children, this approach is less frequently used (Fennell, 1994). However, it may be more cost-effective because of the small number of domains which are assessed (Goldstein, 1997). A major drawback to the idiographic approach is the limited research base which is generated and the inability to verify or study the efficacy of this approach as compared to other approaches.

4.10.2.5.3 Combined approaches

The most frequently used approach represents a combination of the nomothetic and idiographic approaches and has been referred to as the flexible battery approach (Sweet et al., 1996). A core set of the same tests is administered to all children, as in the nomothetic approach, and serves as the basis for initial hypothesis generation; this may constitute an initial screening battery. To this core set, further tests are added that are specific to the referral question or that are believed, based on initial observations and performance, to enhance the information provided (Bauer, 1994; L. C. Hartlage & Telzrow, 1986; Rourke, Fisk, & Strang, 1986). The components of the flexible battery itself generally reflect the theoretical position taken by the neuropsychologist with regard to the manner in which behavioral performance reflects brain pathology and the reasons for referral for neuropsychological evaluation for a given individual (Bauer, 1994). According to surveys completed in the 10 years since 1987, the flexible battery approach is generally that preferred by neuropsychologists working with populations of varying ages (Sweet & Moberg, 1990; Sweet et al., 1996). This approach is believed to more accurately identify specific deficits (Batchelor, 1996b).

The Boston Process Approach (Kaplan, 1988; Lezak, 1995) is one example that incorporates a flexible battery. Specific measures with low specificity are used to assess multiple constructs in a variety of neuropsychological domains (Batchelor, 1996b). Hypotheses are then made based on the initial measures, and additional measures with higher levels of specificity are then selected and used to differentiate within and between various functions. Hypotheses initially generated from the screening battery are thus either confirmed or nullified. Inferences are then made regarding brain function based on the specific deficits identified. The flexible battery used in the Boston Process Approach is not limited to quantitative data but also includes qualitative information that is believed to be important in

Table 3 Luria Nebraska Neuropsychological Battery-Children's Revision.

Scale	*Description*	*Function(s) assessed*
C1 (motor)	Items cover a variety of motor skills (bilateral and unilateral) including simple hand movements, drawing, and constructional skills.	These tests measure motor domains but are sensitive to many types of motor problems. (Golden, 1997).
C2 (rhythm)	Items include a variety of tasks in which the child is required to report whether one of two groups of tones is higher or lower, reproduce tones and rhythmic patterns, and identify the number of beeps in groups of sounds.	These items are considered to be most sensitive to attention and concentration (Golden, 1997).
C3 (tactile)	Items include tasks in which the child is asked to report where they are touched, how hard they are touched, as well as to name and identify objects through touch.	These items measure the extent of cutaneous sensation and stereognostic perception (Golden, 1997).
C4 (visual)	Items include tasks in which the child is required to identify an object or picture, overlapping pictures, pictures that are difficult to perceive, and mirror image versions; items also include progressive matrices, and spatial rotation.	These items measure visual–spatial organization and perception as well as right hemisphere function (Golden, 1997).
C5 (receptive speech)	The child is required to repeat phonemes, repeat phonemes at various levels of pitch, name objects, point to objects, identify and define words, and respond to sentences.	These items measure receptive language and auditory skills as well as left hemisphere function (Golden, 1997).
C6 (expressive speech)	The child is required to repeat phonemes, words, and sentences as well as to generate speech forms including naming objects, counting forward and backward, spontaneous discourse in response to a picture, story, or discussion topic.	These items measure expressive language as well as left hemisphere function. Results may be impacted by reading ability (Golden, 1997).
C7 (writing)	Tasks include copying of letters and words, writing first and last name, writing sounds, words, and phrases from dictation.	These items measure visual motor and auditory motor skills and are believed to measure functioning of the temporal–parietal–occipital area (Golden, 1997).
C8 (reading)	The child is asked to generate sounds from letters, name letters, read simple words, sentences, and paragraphs.	These items measure reading as well as left hemisphere function (Golden, 1997).
C9 (arithmetic)	Child is asked to write arabic and roman numerals from dictation, compare numbers, complete simple computation problems, and generate serial threes.	These tasks measure arithmetic skills, but are considered the most sensitive to educational deficits as well to all/any dysfunction (Golden, 1997).
C10 (memory)	Tasks required include having the child memorize words as well as predicting their own performance on various memory tasks.	These items measure short-term memory functions and are most sensitive to verbal dysfunction (Golden, 1997).
C11 (intellectual)	The child is asked to complete a variety tasks including interpretation of pictures, arranging pictures in order, identification of what is comical/absurd, interpretation of story, determination of similarities, simple arithmetic problems, identification of logical relations and so on.	These are considered to be reflective of general neuropsychological function, concept formation, and reasoning (Golden, 1997).

understanding the child's problems and in developing effective intervention programs (Batchelor, 1996b; Milberg, Hebben, & Kaplan, 1996). There is less of a focus on the results of standardized test performance with greater attention paid to developmental history, presentation of symptoms, strategy use in task completion, and error analysis. As such, the "process" approach uses both standardized measures and experimental measures as well as "testing of limits" that may involve procedural modifications in order to gain insight into brain–behavior relationships (Kaplan, 1988; Milberg, et al., 1996). Concern has, however, been expressed regarding the reliability of scores obtained on standardized measures when the standardization procedures have been compromised (e.g., Rourke et al., 1986). Further, most of the research and clinical study, with the Boston Process Approach in particular, has been with adult populations as opposed to children, and it is not recommended for other than research applications.

4.10.2.6 General Organization of the Neuropsychological Assessment of the Child

When the neurologist examines a child, the physical examination looks principally for structural defects in the CNS, trauma to the CNS, or specific disease entities or toxins. An assessment of history is an integral component of both the neurological and the neuropsychological assessment of children and includes, for the neurologist, assessment of the gestational period, delivery, postnatal history, and the family medical history through at least two generations. The physical examination that lay people view as the neurological examination proper is based largely on observations of the neurologist and is conducted in the context of a brief interview and physical manipulation to assess tone, muscle strength, deep tendon reflexes, sensation, and brain stem and spinal reflexes. Electrophysiologic, serologic and/or imaging studies may then be ordered as may be suggested by such results. Neuropsychological testing may also be ordered when there are suspicions of intellectual delay or functional sequelae are suspected, related to trauma, disease, or toxins. As recently as the 1970s and into the 1980s, neuropsychological testing was used to evaluate lesion site and size and to assist in the differential diagnosis of a variety of neurologic diseases, but this function has been largely supplanted by advances in neuroimaging, clinical serology, and the linking of a variety of cancers to mental symptoms.

The neuropsychological examination of children is focused more directly on an analysis of the functional concomitants and sequelae than on the identification of strictly neurologic disorders, but it is also useful in the diagnosis and identification of more subtle conditions (e.g., learning disabilities, ADHD) or other neurologic disorders, especially in early stages (such as childhood onset of Huntington's disease) that are more resistant to diagnosis via neurologic examination. (In adulthood, differential diagnosis, such as depression versus dementia or differentiation of malingering or among various dementias takes on greater importance.) At all ages, the neuropsychological examination is also focused on rehabilitation.

A thorough history is important to a proper neuropsychological assessment. The length of time since trauma or disease onset, premorbid levels of functions, family history of related problems, and problems related to gestation, delivery, and the postnatal period are all relevant to accurate interpretation of the results of neuropsychological testing. If a school-aged or college-aged individual is involved, it is important to review educational history with specific performance data including standardized tests scores and grades along with any special education history. With children who are, developmentally, a moving target, it is important to be always cognizant of the educational implications of the reason for referral. Following a review of history and obtainable records, there are nine key points to consider in the organization of the neuropsychological assessment.

(i) *All or at least a significant majority of the child's educationally relevant cognitive skills or higher order information process skills should be assessed.* This will often involve an assessment of general intellectual level via a comprehensive IQ test such as a Wechsler scale or KABC. Evaluation of the efficiency of mental processing as assessed by strong measures of g, is essential to provide a baseline for interpreting all other aspects of the assessment process. Assessment of basic academic skills including reading, writing, spelling, and math will be necessary, along with tests of memory and learning such as the TOMAL which also have the advantage of including performance-based measures of attention and concentration. Problems with memory, attention and concentration, and new learning are the most common of all complaints following CNS compromise and are frequently associated with more chronic neurodevelopmental disorders (e.g., learning disability, ADHD).

(ii) *Testing should sample the relative efficiency of the right and of the left hemispheres of the brain.* Asymmetries of performance are of interest in their own right, but different brain systems are involved in each hemisphere that have different implications for treatment as well. Even in a diffuse injury such as anoxia, it is possible to find greater impairment in one portion of an individual's brain than in another. Specific neuropsychological tests like those of Halstead and Reitan or the LNNB-CR are useful here.

(iii) *Sample anterior and posterior regions of cortical function*. The anterior portion of the brain is generative and regulatory while the posterior region is principally receptive. Deficits and their nature in these systems will have great impact on treatment choices. Many common tests such as receptive (posterior) and expressive (anterior) vocabulary tests may be applied here along with a systematic and thorough sensory perceptual examination. In conjunction with key point (ii), this allows for evaluation of the integrity of the four major quadrants of the neocortex.

(iv) *Determine the presence of specific deficits*. Any specific functional problems a child is experiencing must be determined and assessed. In addition to those being of importance in the assessment of children with neurodevelopmental disorders, traumatic brain injury (TBI), stroke, even some toxins can produce very specific changes in neocortical function that are addressed best by the neuropsychological assessment. Similarly, research with children with leukemia suggests the presence of subtle neuropsychological deficits following chemotherapy that may not be detected by more traditional psychological measures. Neuropsychological tests tend to be less *g*-loaded as a group and to have greater specificity of measurement than many common psychological tests. Noting areas of specific deficit is important in both diagnosis and treatment planning.

(v) *Determine the acuteness versus the chronicity of any problems or weaknesses found*. The "age" of a problem is important to diagnosis and to treatment planning. Combining a thorough history with the pattern of test results obtained, it is possible, with reasonable accuracy, to distinguish chronic neurodevelopmental disorders such as dyslexia or ADHD from new acute problems resulting from trauma, stroke, or disease. Care must be taken especially in developing a thorough, documented history when such a determination is made. When designing intervention/treatment strategies, rehabilitation and habilitation approaches take differing routes depending upon the age of the child involved and the acuteness or chronicity of the problems evidenced.

(vi) *Locate intact complex functional systems*. It is imperative in the assessment process to locate strengths of the child and intact systems that can be used to overcome the problems the child is experiencing. Treatment following CNS compromise involves habilitation and rehabilitation with the understanding that some organic deficits will represent permanently impaired systems. As the brain is a complex interdependent systemic network of complex organizations that produce behavior, the ability to identify intact systems is crucial to enhancing the probability of designing successful treatment. Identification of intact systems also suggests the potential for a positive outcome to parents and teachers, as opposed to fostering low expectations and fatalistic tendencies on identification of brain damage or dysfunction.

(vii) *Assess affect, personality, and behavior*. Neuropsychologists sometimes ignore their roots in psychology and focus on assessing the neural substrates of a problem. However, CNS compromise will result in changes in affect, personality, and behavior. Some of these changes will be transient, some will be permanent, and due to the developmental nature of children, some will be dynamic. Some of these changes will be direct (i.e., a result of the CNS compromise at the cellular and systemic levels) and others will be indirect (i.e., reactive to loss or changes in function, or to how others respond to and interact with the individual). A thorough history, including onset of problem behaviors, can assist in determination of direct versus indirect effects. Comprehensive approaches such as the Behavior Assessment System for Children (BASC; Reynolds & Kamphaus, 1992) which contain behavior rating scales, omnibus personality inventories, and direct observation scales seem particularly useful. Such behavioral changes will also require intervention and the latter may vary depending on whether the changes noted are direct or indirect effects or whether there were behavior problems evident on a premorbid basis.

(viii) *Test results should be presented in ways that are useful in school settings, not just in acute care or intensive rehabilitation facilities*. Schools are a major context in which children with chronic neurodevelopmental disorders must function. Children who have sustained insult to the CNS (i.e., TBI, stroke) will eventually return to a school or similar educational setting. Schools are where the greatest long-term impact on a child's outcome after CNS compromise is seen and felt. Results should speak to academic and behavioral concerns, reflecting what a child needs to be taught next in school, how to teach to the child's strengths through the engagement of intact complex functional systems, and how to motivate and manage positive behavioral outcomes. For children with TBI, additional information regarding potential for recovery and the tenuousness of evaluation results immediately post-injury needs to be communicated as does the need for reassessment of both the child and the intervention program at regular intervals.

(ix) *If consulting directly to a school, be certain the testing and examination procedures are efficient*. School systems, which is where one finds children, do not often have the resources for funding the type of diagnostic workups neuropsychologists prefer. Therefore, when consulting to the school, it is necessary to be succinct and efficient in planning the neuropsychological evaluation. If the school can provide the results of a very recent intellectual and academic assessment as well as the behavioral assessment information, this can be then integrated into the neuropsychological assessment by the neuropsychologist. If a recent intellectual and academic assessment has not been completed, it may be cost-efficient for qualified school district personnel to complete this portion of the assessment for later integration with other data obtained and interpretated by the neuropsychologist. For children in intensive rehabilitation facilities or medical settings, it may be appropriate for school personnel to participate in the evaluation prior to discharge (i.e., for children with TBI being released and returned to the schools). This collaborative involvement can facilitate program planning with the receiving school district and is preferable to eliminating needed components of the neuropsychological evaluation.

When considering rehabilitation of the child with a focal injury or TBI, several additional considerations are evident. It is important to determine what type of functional system is impaired. Impaired systems may, for example, be modality-specific or process-specific. The nature or characteristics of the impairments must be elucidated before an intelligent remedial plan can be devised.

The number of systems impaired should be determined and prioritized. Children may not be able to work out everything at once and a system of priorities should be devised so that the most important of the impairments to impact overall recovery is the first and most intensely addressed area of impairment. The degree of impairment, a normative question, is also an important consideration in this regard. At times, this will require the neuropsychologist to reflect also on the indirect effects of a TBI, as an impaired or dysfunctional system may adversely affect other systems that are without true direct organic compromise.

The quality of neuropsychological strengths that exist will also be important and tends to be more of an ipsative as opposed to a normative determination. Furthermore, certain strengths are more useful than others. Preserved language and speech are of great importance for example, while an intact sense of smell (an ability often impaired in TBI) is of less importance in designing treatment plans and outcome research. Even more important to long-term recovery are intact planning and concept formation skills. The executive functioning skills of the frontal lobes take on greater and greater importance with age, and strengths in those areas are crucial to long-term planning (as is the detection of weaknesses). These will change, however, with age as the frontal lobes become increasingly prominent in behavioral control after age nine years, again through puberty, and continuing into the 20s.

There are of course times when the scope of the neuropsychological assessment of a child is less broad. On occasion, referrals may be very specific (e.g., "Does Susan have memory or attention problems?). Even when such seemingly succinct questions are asked, it is commonly a good practice to inquire of the referral source as to whether other questions may be anticipated (e.g., Is memory an issue because of poor school achievement? Possible learning disability?).

This section draws in part upon the writings, teachings, and workshops of Lawrence C. Hartlage and Byron Rourke.

4.10.2.7 Interpretation Issues

Neuropsychological assessment of children yields not only an accumulation of test data and impressions, but also a variety of paradigms for understanding and interpreting that data. There are a number of competing paradigms and theories (e.g., Ayers, 1974; Das et al.,and 1979; Luria, 1966; Reynolds, 1981b), and as a result, not only is there considerable variability in the quality and choice of measures used in the neuropsychological assessment of children, there are considerable differences in the ways in which the data obtained are used for making inferences and eventually interpreted (Batchelor, 1996a; Nussbaum & Bigler, 1997). Interpretation of the accumulated data is dependent to a great extent on the neuropsychologist's clinical skills and acumen (D'Amato et al., 1997). Interpretation may be based on overall performance level (e.g., Reitan, 1986, 1987), performance patterns (e.g., Mattarazzo, 1972; Reitan, 1986, 1987), asymmetry of function (e.g., L. C. Hartlage, 1982), the presence of "organic" signs (Kaplan, 1988; Lezak, 1995), or on some combination of features. It is not necessarily the case that only one paradigm is appropriate; which paradigm is most suitable may depend on the child being evaluated. Most importantly, the model used for interpretation should allow the neuropsychologist to make predictions about the child's ability to perform in a variety of contexts and about the efficacy of treatment/intervention plans (Reynolds et al., 1997).

4.10.2.7.1 Performance level

With the use of this indicator, the child's overall level of performance is compared to normative data and conclusions are reached based on deviations from the norm. The extent of variability among typically developing children on some measures at given ages (e.g., when the standard deviation approximates the mean score) may preclude interpretation of results using this approach. In addition, this approach can be misleading, particularly in those individuals with higher cognitive ability (Jarvis & Barth, 1984; Reitan & Wolfson, 1985). Further, there is a tendency for this method to yield a large number of false positives due to the potential for other factors (e.g., motivation, fatigue) to impact on a child's performance (Nussbaum & Bigler, 1997).

4.10.2.7.2 Profile patterns

Application of the neuropsychological model to learning problems has been criticized as being too aligned with a medical model and an emphasis on pathology (Gaddes & Edgell, 1994). As asserted by Little and Stavrou (1993), merely identifying that brain integrity has in some way been compromised is not in and of itself particularly helpful to the child or to those who need to develop interventions to help the child. Neuropsychologists look beyond diagnosis or categorization to an understanding of brain–behavior relations. In order to accomplish this, neuropsychological assessment involves consideration of associations and dissociations of performance across measures (Fletcher, 1988; Rutter, 1981). Performance patterns or intraindividual differences provide a means of conceptualizing functional vs. dysfunctional organizational systems. Strengths and weaknesses are then identified based on the discrepancies between the domains studied. This method has, however, been used frequently for the identification or classification of subtypes of learning disabilities (Branch et al., 1995; Nussbaum & Bigler, 1986; Rourke, 1984).

In interpreting data obtained using this type of evaluation, clinicians differ with regard to emphasis on child strengths, child weaknesses or a combination of strengths and weaknesses (L. C. Hartlage & Telzrow, 1983; Reynolds, 1981b, 1986a; Teeter, 1997). It has been argued that a strength model is more efficacious, with habilitation based on those complex functional systems that are sufficiently intact, and therefore potentially capable of taking over and moderating the acquisition of the skills needed (Reynolds et al., 1997). Emphasis on weaknesses, generally referred to as the deficit model, is not supported by research (e.g., Adams & Victor, 1977; L. C. Hartlage, 1975; P. L. Hartlage & Givens, 1982; P. L. Hartlage & Hartlage, 1978), and deficit approaches to intervention (e.g., remediation of the deficit process) have not been found to be effective and may even be harmful (L. C. Hartlage & Reynolds, 1981).

There are, however, some problems with this method of interpretation regardless of whether the focus is on strengths, weaknesses, or a combination of these. This approach may be misleading as other variables may account for these intra-individual differences (Jarvis & Barth, 1984). Additionally, some such intra-individual differences (e.g., verbal IQ–performance IQ differences) have been found to occur with frequency in the general population (e.g., Kaufman, 1976b) and seemingly abnormal levels of subtest scatter (WISC-R) have been found to be relatively common (Gutkin & Reynolds, 1980; Kaufman, 1976a, 1976b; Reynolds, 1979). Base rates in the general population of specific intra-individual differences for various other combinations of measures have not been studied, and what appears to be a "difference" may not be unusual or unique at a given age level. Further, the stability of these profile patterns over at least very short periods of time needs to be investigated (Reynolds, 1997b).

4.10.2.7.3 Functional asymmetry

Examination of asymmetries in performance across measures is another method of intra-individual consideration. Replicable asymmetries in performance are generally considered signs of CNS dysfunction (Batchelor, 1996b). Most frequently, the comparison is made between those functions that are believed to be right hemisphere-dominated as opposed to left hemisphere-dominated. These differences, however, may be difficult to interpret, particularly for younger children (Reynolds et al., 1997). Further, understanding of the lateralization of cortical functions is frequently based on evidence from adults as opposed to children and assumes that the lateralization is stable over time, despite differing rates of brain maturity (Spreen et al., 1995). Reliance on left–right differences and measures based on lateralization of function have also been criticized as ignoring the role of hemispheric interaction on behavior (e.g., Efron, 1990; Hiscock & Kinsbourne, 1987).

As with the patterns of performance method, right–left differences have been used in the characterization of children with right hemisphere dysfunction as suggestive of learning disability or ADHD (Rourke, 1989). The results of studies are, however, equivocal (e.g., Branch et al., 1995; Gross-Tsur, Salev, Manor, & Amir, 1995; Voeller, 1995). Research, in general, regarding lateralization of function and hemispheric specialization is fraught with conflicting results (e.g., Bever, 1975; Das et al., 1979; Dean, 1984; Reynolds, 1981b), and it has been suggested that the traditional verbal–nonverbal distinction between hemispheres is an oversimplification of a complex system (Dean, 1984; Reynolds, 1981a). Based on Luria's theories, asymmetries of function are not content- or modality-specific but rather are "process"-specific (Reynolds, 1981a, 1981b). Bever (1975) posited two fundamental lateralized processing types, the analytic and holistic; these were translated into sequential and simultaneous in the KABC based on Das et al. (1979). In the research literature, however, there is often a preponderance of emphasis placed on content and modality, as opposed to process, in the interpretation of functional asymmetries; it is believed that this may account for the conflicting results across studies (Reynolds et al., 1997).

Nussbaum et al., (1988) proposed an alternate method of examining asymmetry. In the model of Nussbaum and colleagues, the neuropsychological protocol and interpretation reconceptualized neurobehavioral functioning along the anterior–posterior gradient as opposed to left–right differences. The recommended protocol includes tasks from the HRNB as well as from other batteries. Nussbaum and colleagues asserted that this model may provide additional information in the investigation of asymmetries in children with learning and behavioral problems. Initial research in this area suggested that weaknesses on anterior measures were associated with psychological/behavioral problems (Teeter & Semrud-Clikeman, 1997). Two later studies, however, failed to support the anterior–posterior gradient theory (Matazow & Hynd, 1992)

4.10.2.7.4 Pathognomonic signs

The pathognomonic signs approach involves the identification of specific deficits or performance errors that are not frequently found in typically developing individuals (Nussbaum & Bigler, 1997). Identification of "organic" signs is generally completed through qualitative analysis of errors (Kaplan, 1988; Lezak, 1995). The presence of specific types of errors is then seen as an indication of a compromise to brain integrity. This method has been used reliably with adult populations; however, the utility of this approach in the neuropsychological assessment of children has not been demonstrated (Batchelor, 1996b). The range of variability associated with the developmental process in children would seem to make it more difficult to interpret specific errors as signs of organic impairment (Nussbaum & Bigler, 1997). Unlike the performance levels method, the use of pathognomonic signs has been found to result in a large number of false negatives (Boll, 1974). This may be related to the potential for reorganization/recovery of function in children (Nussbaum & Bigler, 1997).

4.10.2.7.5 Combination approaches

Boll (1981) proposed utilizing performance levels, patterns of performance, pathognomonic signs, and asymmetry of function in concert, in order to account for the potential limitations to the use of any single approach in the interpretation of neuropsychological assessment data. This multiple inferential levels approach is used in the HRNB and is supported by others as well (e.g., Rourke, 1994). The "rules approach" (Selz & Reitan, 1979b) also combines approaches, but in a different manner. Using the "rules approach," each of 37 aspects of neuropsychological performance is rated on a four-point scale in order to provide an objective system for measuring the extent of impairment.

More recently, Taylor and Fletcher (1990) proposed that the child's performance on neuropsychological measures be used to identify and clarify the functional aspects of the child's problems, with the understanding that the biological or neurological substrates of the learning or behavior problem serve to set limits on the child's performance. Levine (1993) has posited still another model for interpretation of neuropsychological data. The "observable phenomenon" model places the emphasis on observable behaviors, that may impact on classroom performance and the changing demands placed on the child over time, as opposed to test results.

4.10.3 CONCLUSIONS

Neuropsychological assessment and the field of clinical child neuropsychology in general have much to offer in the way of understanding the functional systems of the brain and the mechanisms involved in the learning and self-regulation process. Not only is this important in understanding and designing treatment programs for children with problems, but increased understanding of brain functions and their relation to behavior can also improve the overall outcomes for all children (Gaddes, 1983). Historically, neuropsychological assessment of children has taken its lead from research and practice with adults. Issues relating to neurodevelopment, task appropriateness, varying contexts for children, progression following brain injury with children, and so on, render the continuing use of this approach inappropriate. A variety of theoretical models exist; however, many of these are adult-based and used without consideration of developmental issues. Only by developing its own theories and clinical assessment procedures, that are sensitive to developmental features and responsive to educational issues, can the field of clinical child neuropsychology continue to advance and make meaningful contributions to the understanding of learning and behavior problems in children. Development and incorporation of typologies within the childhood disorders, based on clinical experience with children and neuropsychological theory that addresses habilitation, programming, and research needs and that has intuitive appeal to psychologists, educators, and neurologists, would be viewed as a major conceptual contribution to the field of child neuropsychology (Reynolds, 1986b).

Continued methodological and measurement problems in the research that serves as a foundation for the interpretation of neuropsychological data impede progress in the field of clinical child neuropsychology and impact on the accuracy of diagnosis and on the appropriateness of treatment planning. Lack of attention to standard psychometric methods within the field of clinical neuropsychology is all too rampant and poses serious limitations in research in clinical arenas; intuitive appeal, clinical acumen, and perceived utility are not sufficient, but must be combined with sound empirical research (Reynolds, 1986b). While it is anticipated that new measures will have sufficient normative samples for evaluation of associations with demographic variables, and assessment of validity, reliability, sensitivity, and specificity issues, many existing measures continue to have insufficient normative data. All too often, sensitivity is a focus; specificity is also necessary if results are to be useful in treatment/intervention planning. This requires further investigation of contrasting clinical groups. In research with clinical groups, there is a need to consider comorbidity and be as specific as possible in descriptions of clinical subgroups (e.g., Fletcher, Shaywitz, & Shaywitz, 1994). Regardless of the perspective used in interpretation, the value of that interpretation is only as good as the measures used in the assessment process and their sensitivity and specificity (Batchelor, 1996b) in combination with the skills and knowledge of the user (Golden, 1997). Failure to resolve these measurement and methodology issues has impeded and will continue to impede progress in the field of neuropsychology (Reynolds, 1997b).

The field of clinical child neuropsychology is in part driven by the development and application of standardized diagnostic procedures that are sensitive to higher cognitive process as related to brain function (Reynolds, 1997b). While the development of new measures of memory, attention, information processing, and so on provide alternatives for clinical child neuropsychologists (e.g., Reynolds, & Bigler, 1994), further research is needed with these as well as with other new and existing measures in order to determine their utility as part of a comprehensive neuropsychological battery. The incorporation of computer-based assessment is likely to increase in the next decades with the potential for incorporation of computer simulation, interactive types of tasks, virtual reality and so on, as means of measuring neuropsychological function. Computerized testing may facilitate the interface with electrophysiological and neuroradiological methods and, ultimately, bring about significant advances in the understanding of learning and behavior problems. Technological advances in assessment, however, will require the same types of research regarding psychometric properties, confounding factors, cultural/gender differences, and so on. Even with those existing tests that currently include an option for computerized assessment, there are some indications of differences in results following computer administration as opposed to the more traditional administration. If this is the case, then it may be appropriate for separate normative data to be obtained for each mode of administration. Furthermore, children with substantial CNS compromise will have difficulty manipulating computerized test materials, and careful validity research will be required at a time when publishers and others are looking for ways to reduce costs associated with health care products.

A major concern with regard to the increased emphasis on reducing health care costs is that neuropsychologists will shorten tests and attempt to streamline batteries, and in the process lessen both the quantity of time required and the quality of the assessment provided (Woody, 1997). This not only impacts on clinical practice, but also on the knowledge generated through future research. Conflict or dissonance among clinicians will not be well tolerated and the future of clinical child neuropsychology will need the support of public policy (Woody, 1997). This means that reasonable agreement on theoretical foundations, training, and procedures will need to be reached (Woody, 1997). Provision of neuropsychological services needs to be predicated on academics, research, and training consistent with both a clinical psychology orientation and specialized training in brain–behavior relationships, in order to ensure sound foundations (Woody, 1997). With regard to neuropsychological assessment of children, there is a definite need on the part of child neuropsychologists to be well grounded in the developmental process, from a cognitive as well as neurological perspective. Children are a moving target and need even more sophisticated assessment devices than do adults. Considerable work remains in this domain alone.

Neuropsychological assessment of children with learning or behavioral/emotional problems is not necessarily essential. It does, however, provide for a comprehensive evaluation of cognitive skills and emotional factors as well as of environmental influences (L. C. Hartlage & Long, 1997). Neuropsychological assessment may be most appropriate for those children who exhibit characteristics of a disorder that includes cognitive deficits (e.g., learning disability) or significant behavioral problems (e.g., behavior disorder) in the absence of neurophysiological evidence of brain damage, for those with a known neurological syndrome or disease as evidenced by neurophysiological methods, and for those children who, because of genetic predisposition or prenatal/perinatal complications, are believed to be at high risk for neurological disorders (Allen, 1989).

4.11.1 INTRODUCTION

Clinical neuropsychology represents one of the most rapidly growing areas within the field of psychology and was one of the first to gain specialty status by the American Psychological Association in 1996. At a basic level, the neuropsychological examination represents a combination of the traditional behavioral neurologic examination with a psychometric approach to the evaluation of brain–behavior relationships. From the broader field of psychology, neuropsychology derived its emphasis in the application of psychometric procedures to quantify behavior. From its other parent discipline of neurology came the interest in evaluating brain function. The term "neuropsychology" originally evolved in the 1930s and 1940s and its popularization is often attributed to Hans-Lukas Teuber. Many early neuropsychological procedures were developed during war time to assess cognitive status and suitability of individuals for special military service. Subsequently, penetrating missile wounds to the brain became the focus of localization studies. Accordingly, many tests were created with the goal of being sensitive to focal brain insults. Other measures were developed to assess for "organicity," a now archaic term that had been used to grossly refer to brain damage or neurological deficit. Prior to the advent of modern neuroimaging procedures, neuropsychological techniques emerged as a front-line assessment procedure for the identification and localization of acquired cerebral damage. While neuropsychological techniques continue to provide this aspect of neurodiagnostic assessment to some extent, more commonly the procedures are used to describe and quantify behavior. The results of these evaluations can be used to infer cerebral integrity vs. dysfunction, to delineate cognitive strengths and weaknesses, and to assist in differential diagnosis. Assisting other professionals in differential diagnostic situations and documenting level of impairment can be a primary role for these evaluations. Other goals of neuropsychological assessment include making treatment and rehabilitation recommendations, assisting in placement issues, and in evaluating treatment response (e.g., in cases of neurosurgical or pharmacological intervention).

The neuropsychological examination can also provide useful information to patients regarding their functioning, and feedback may be used therapeutically in terms of adjustment issues. In many cases, informing the patient that their cognitive difficulties can be documented and explained (or at least are not unexpected) can be most reassuring. Discussing the nature of a disorder and the various cognitive and emotional sequelae it may have, as well as the typical course of recovery or changes that can be expected, is also helpful in terms of setting realistic expectations and goals. Furthermore, presenting information and potential compensatory strategies or interventions that are helpful given a patient's particular situation can be rewarding. In some medical settings in particular, the neuropsychologist may play a central role in helping patients understand the nature of their difficulties by providing this information in understandable terms within an emotionally supportive context.

Among existing neurodiagnostic procedures, the neuropsychological evaluation remains the most sensitive means of assessing human brain function. Knowing the presence and location of a given lesion, for example, provides only limited information about an individual's functioning. For example, the patient in Figure 1 sustained an infarction of the right posterior cerebral artery.

How such a patient might be functioning in his or her daily life, however, remains a question that simple structural neuroimaging cannot address. For example, the individual depicted in Figure 1 might be expected to show a contralateral visual field cut (hemianopsia) based on the location of the lesion, although the impact of this as well as any other associated cognitive processing difficulties would be unknown without clinical examination.

Another example is provided in the case of the 65-year-old patient whose magnetic resonance imaging (MRI) scan is presented in Figure 2. This individual demonstrated grossly normal brain structure, with no major evidence of atrophy or particular neuropathology. Despite the normal appearance of her brain, a severe level of dementia was observed as reflected by her score of 10/30 on the Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975). Although dementia is often associated with cortical atrophy, clinicians should keep in mind that dementia is a clinical diagnosis and the degree of atrophy on neuroimaging shows only a modest association

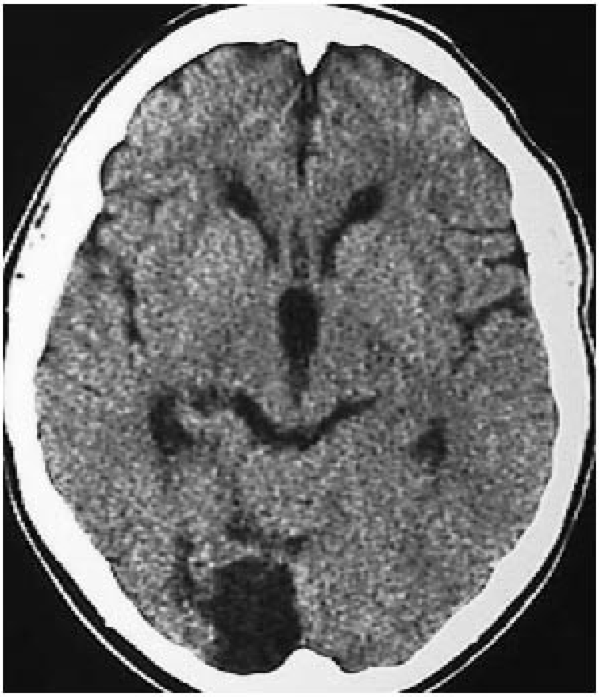

Figure 1 CT scan depicting posterior right hemisphere lesion (note that right is depicted on the left).

with level of cognitive impairment (Naugle, Cullum, Bigler, & Massman, 1986).

Given the utility of neuropsychological techniques in terms of documenting and understanding the neurobehavioral sequelae of cerebral dysfunction, a discussion of some of the major approaches and common measures used in clinical neuropsychology is in order.

4.11.2 APPROACHES TO ASSESSMENT IN CLINICAL NEUROPSYCHOLOGY

Contemporary clinical neuropsychology owes a debt to many of its early founders, and because of the youth of the field, many of these individuals remain heavily involved in the field. A listing of the major contributors to the field of clinical neuropsychology is beyond the scope of this chapter and involves a wide variety of individuals from different theoretical backgrounds and disciplines. In terms of major contributors to the development of neuropsychological assessment, such a list would have to include the following: Benton, Butters, Goldstein, Goodglass, Halstead, Kaplan, Meier, Parsons, Reitan, and Spreen. Citations and representative examples of their work can be found in various textbooks and merit review by those interested in obtaining more information about clinical neuropsychology (e.g., see Grant & Adams, 1996; Lezak, 1995; Naugle, Cullum, & Bigler, 1998; Spreen & Strauss, 1998).

The concept of "approaches" to neuropsychological assessment can be considered from several perspectives. Historically, the "fixed" vs. "flexible" test battery approach was a topic of discussion and even heated debate for many years. Since many contemporary neuropsychologists tend to utilize a "core" battery of favorite measures for many of the patients they examine, but modify the assessment by adding or deleting specific tests depending upon the clinical population and/or referral issues in question, this has become an essentially moot issue. Furthermore, the modification of even the most "fixed" of test batteries to address individual patient needs and referral questions is now commonplace. Thus, the distinction between fixed and flexible approaches to neuropsychological assessment is somewhat arbitrary, although some discussion of the central issues involved in test selection and the composition of "standard" or core test batteries is in order.

4.11.2.1 The Standard Battery

In its strictest sense, a fixed standard battery approach involves the administration of the same set of tests to all patients, regardless of

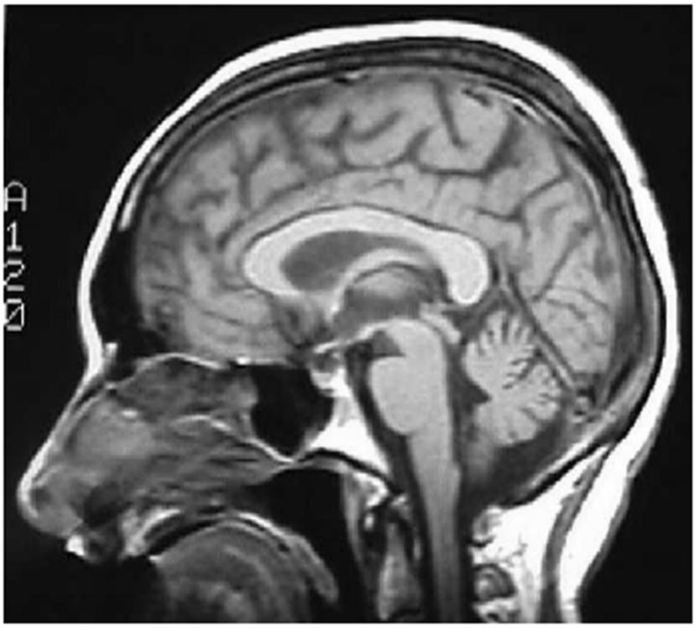

Figure 2 MRI depicting normal gross brain structure in a patient with severe dementia.

diagnostic or referral question, level of impairment, patient complaints, or clinical presentation. Applied too rigidly, such an approach may not yield appropriately detailed information regarding a specific area of deficiency (e.g., memory) unless that ability area is adequately represented in the standard or core battery. The application of an extensive omnibus test battery to all individual cases may also prove less efficient in some instances by oversampling behavior. For example, in the case of a rigid standard battery, a lack of impairment on a higher level ability measure may be followed by the routine administration of a similar task that tends to be less sensitive to deficits in that same domain. However, it has also been argued that a standard battery approach may allow for a broader assessment of neurobehavioral abilities in some settings, and hence, may detect cognitive impairment that a less comprehensive battery might miss. For example, a patient referred for memory assessment might be administered only a test of global intelligence (e.g., Wechsler Adult Intelligence Scale-Revised; WAIS-R) and selected measures of memory (e.g., the Logical Memory and Visual Reproduction subtests from one of the versions of the Wechsler Memory Scale are commonly used in various settings). Such an evaluation may not be sensitive to deficits in executive functioning or higher-order cognitive integration that might be manifest upon more detailed assessment and that can impact memory test performance. It should be noted, however, that the limited comprehensiveness of the battery would be a more important issue than whether this represents a fixed or more flexible assessment approach.

Perhaps the best example of a standard neuropsychological battery is the group of tests that was originally created in the 1940s by Ward Halstead and further developed by one of his most prominent students and colleagues, Ralph Reitan. Halstead had strong interests in the assessment of biological intelligence and in the quantification of brain–behavior relationships, particularly at a time when localization of cerebral lesions was often a focus of neuropsychological evaluations. The work of Halstead and Reitan contributed monumentally to the development of American neuropsychology, and the Halstead–Reitan Neuropsychological Battery (HRB) continues to be used in many settings, whether used *in toto* or by its component tests.

The core HRB consists of the following tests and the primary corresponding cognitive functions (also see Dodrill, 1997): Category Test (abstract reasoning, logical analysis), Tactual Performance Test (complex psychomotor problem solving); Trail Making Test (psychomotor speed and cognitive sequencing); Aphasia Screening Test (brief assessment of language and graphomotor construction); Speech Sounds Perception Test (verbal/auditory attention); Seashore Rhythm Test (nonverbal auditory attention); Finger Tapping Test (fine motor speed); Grip Strength (gross motor strength); Sensory-Perceptual Examination (basic sensory and perceptual abilities); and Tactile Form Recognition (sensory perception, agnosia). Composite summary indices from the core

HRB can also be calculated in order to provide an overall index of cognitive impairment. These include the General Neuropsychological Deficit Scale (GNDS), which is derived from 42 scores from the HRB (0 = no impairment to a maximum possible score of 168; see Reitan & Wolfson, 1993), the Average Impairment Rating (Russell, Neuringer, & Goldstein, 1970) which ranges from 0.00 (no impairment) to 5.00, and the original Halstead Impairment Index (HII; Halstead, 1947), which utilizes a proportion of HRB test results based upon cutoff scores from selected tests (0.0 = no impairment to 1.0, reflecting impairment on all of the key variables). Like IQ scores, such summary indices suffer from a number of limitations (e.g., see Lezak, 1995, pp. 23–24), although they can arguably provide some useful reference information regarding an individual's overall functioning if not overinterpreted or used too rigidly.

Reitan and Wolfson (1996) provide a detailed overview of the HRB in terms of its application and interpretation, and many of the assessment and interpretation issues they discuss have relevance beyond the HRB *per se*. For example, the authors include a discussion of four of the principal ways in which test data can be interpreted: (i) level of performance; (ii) pathognomonic signs (i.e., specific test findings/deficits that strongly suggest brain dysfunction and are uncommon in nonbrain injured subjects; (iii) patterns of test results (e.g., those typifying different disorders); and (iv) comparison of test results using each side of the body (e.g., right vs. left hand) to examine hemispheric lateralization issues.

Clinicians vary with respect to their relative reliance upon each of these interpretive strategies, and depending upon the case, some findings may need to be given greater weight than others. For example, the pathognomonic sign of focal motor weakness in the absence of a peripheral motor injury clearly merits careful attention to the possibility of contralateral cerebral dysfunction. Similarly, a visual field cut (e.g., hemianopsia) should alert the clinician to focal cerebral involvement in the appropriate corresponding neuroanatomical area.

In other cases, the pattern of test results can be more important than the level of performance. Test findings that fall technically within normal limits may show a pattern that is suggestive of cerebral dysfunction. To illustrate this point using a more familiar measure, a patient may demonstrate overall scores within normal limits on the WAIS-III or WAIS-R, yet show relative weaknesses on those subtests most sensitive to cerebral dysfunction which may reflect neurologically-based deficits. Similarly, a normal summary score on other neuropsychological tests can occur even when subscores and/or qualitative performance characteristics suggest clear abnormality or demonstrate a pattern consistent with a particular disorder.

In practice, many clinicians who utilize the HRB administer a modified version of the battery that selectively includes individual HRB tests. For example, many settings that do not routinely use the core HRB nevertheless administer the Category Test as a measure of higher-order problem-solving and because of its high sensitivity to cerebral dysfunction. Alternatively, clinical evaluations relying upon the complete HRB often include additional measures to provide a more detailed assessment of areas of cerebral functioning not well represented in the core battery. For example, one area that often is supplemented is memory, since the core HRB does not provide much in the way of memory assessment, even though this represents a common complaint among neurological populations.

Luria's Neuropsychological investigation (Christensen, 1984) represents a battery of measures that involves the systematic application of the assessment techniques originally described by Luria (1966). The battery is organized into various sections assessing an array of abilities, including basic and higher-level motor functions, receptive and expressive language, memory, and higher-order thinking. Even though it is presented here as a "standard" battery, it involves a sequential hypothesis-testing approach that includes a variety of individual tasks and relies upon qualitative judgments. Many clinicians utilize some of the component tasks selectively in their examinations. Some of the more commonly used tasks are the "go-no-go" paradigm (e.g., "When I hold up one finger, you hold up two," and vice-versa) and what has come to be called the "Luria 3-step" motor sequence by some (i.e., rapidly alternating the hand from flat to fist to edge) in order to assist in the examination of aspects of executive functioning and cognitive initiation/inhibition.

A very different type of standard test battery involves computer administration. Although several such test batteries exist, one example is the Microcog: Assessment of Cognitive Functioning (Powell et al., 1993). This is a computer-administered and scored battery of tests designed to screen for gross cognitive impairment in adults. It is available in short and long forms consisting of 12 and 18 subtests that assess the following general areas: attention/mental control, memory, reasoning/calculation, spatial processing, and reaction time. The test software calculates standard scores and percentile comparisons using age-referenced norms that range from 18 to 89. While Microcog may be useful in some screening situations, the limitations of the brief and selective nature of the tasks, the lack of alternate forms, and the limitations inherent in computer-based assessment must be carefully considered in light of the specific clinical questions and patient populations in need of evaluation.

4.11.2.2 Test Batteries for Specific Populations

Various standard test batteries have been developed and/or assembled for specific purposes and populations, and many of these are reviewed in the excellent neuropsychological test compendiums by Spreen and Strauss (1998) and Lezak (1995). A few of the more commonly used batteries include the following:

(i) The consortium to establish a registry for Alzheimer's disease (CERAD) neuropsychological assessment battery (Morris, Heyman, Mohs, et al., 1989) was developed for use in patients with known or suspected dementia. This is a 30–45 minute examination of cognitive skills that includes measures of orientation, verbal fluency, naming, verbal learning and memory, and graphomotor constructional skills. Good reliability and validity have been demonstrated, and normative data for older adult populations are available (Welsh et al., 1994).

(ii) The NIMH core neuropsychological battery (Butters et al., 1990) was developed to evaluate cognitive changes associated with HIV infection. Both a brief (1–2 hour) and an extended (7–9 hours) battery comprised of standard clinical neuropsychological tests and measures used in cognitive psychology were assembled in order to assess the following cognitive ability areas: premorbid IQ, attention, speed of information processing, learning and memory, abstract reasoning, language, visuoperceptual and graphomotor constructional abilities, and psychomotor skills. It includes tasks that provide information regarding patterns of cognitive deficits as commonly seen in degenerative conditions that affect cortical and particularly subcortical cerebral functions.

(iii) The Pittsburgh Occupational Exposures Test battery (Ryan, Morrow, Bromet, & Parkinson, 1989) was developed to evaluate those cognitive functions most commonly affected by exposure to environmental toxins. It comprises a series of 15 standard and experimental neuropsychological measures that assess a variety of abilities in a reasonably brief amount of time (i.e., approximately 90 minutes). Factor analysis of the battery revealed the following five domains: general intelligence, attention, learning and memory, visuospatial, and psychomotor speed and manual dexterity.

As noted, many neuropsychologists develop their own groups of tests for selected populations, such that a core battery for dementia might have some overlap with a battery for epilepsy (e.g., perhaps in terms of intellectual assessment). Such batteries would likely have different components and stepdown procedures, however. For example, additional or more comprehensive memory measures might be selected for patients with epilepsy when lateralized temporal lobe dysfunction is known or suspected. Furthermore, an assessment of academic achievement skills would typically be more important in the young adult with epilepsy than in the older individual with Alzheimer's disease. Thus, the issue of "core" test batteries depends largely upon neuropsychological training and experience, and many clinicians will use somewhat different sets of tests for different populations. In any case, it is important for the neuropsychologist to be familiar with a wide array of neuropsychological measures, not only in order to stay current with new test developments and research, but also to have a large test repertoire from which to select measures for individual or unique cases, as well as to be best prepared to review test results from other centers.

4.11.2.3 The Hypothesis-driven Approach

The hypothesis-driven or more flexible approach to neuropsychological assessment espouses the selection of tests based on referral questions, known or suspected diagnoses/pathology, and individual patient complaints and symptom presentation. Such examinations tend to be more "customized" or individually tailored, even though a relatively standard "core" battery of tests may be included as part of the evaluation. Tests may also be added or removed from the planned evaluation as the testing process progresses, depending upon performance results and patterns of strengths and weaknesses observed on various measures. As noted, many neuropsychologists administer a core group of tests to many or most of the patients they examine, subsequently tailoring aspects of the evaluation to follow up on areas of particular clinical interest. For example, a patient referred for evaluation of memory complaints might undergo a standard battery of measures that provides an evaluation of multiple cognitive domains, although the focus of the examination might be a more extensive assessment of various aspects of memory designed to thoroughly examine the patient's complaints or known/suspected pathology. Care must obviously be used in test selection, lest an examination become too cursory or overly focused, or, at the other extreme, too lengthy and redundant. For example, an examination that consisted only of memory measures to evaluate a patient's memory complaints would neglect other areas of functioning (e.g., attention/concentration, executive functioning, language disturbance) that might play a prominent role in an individual's complaints of memory problems. Another issue is that once an area of deficiency is identified, the question arises as to how much exploration/assessment of the deficit is necessary. Certainly addressing the referral question is of great importance, and to the extent that this has been addressed, the clinician may decide to stop the evaluation at that point. In other cases, however, such as in the differential diagnosis of Parkinson's disease-related cognitive decline vs. depression vs. early Alzheimer's disease, more detailed exploration of multifaceted aspects of memory and other neurocognitive functioning would be required beyond the question, "Is there evidence of cognitive impairment?" that is often posed in certain settings.

4.11.2.4 Quantitative and Qualitative Examinations of Neurobehavioral Competence

Quantitative assessment refers to the use of test scores for interpretation, and qualitative examination often refers more to observations that pertain to the process by which patients perform tasks. To illustrate this latter point, even though a particular score on a test reflects a certain level of proficiency, that level of achievement may be attained via different cognitive strategies. An inefficient trial-and-error approach to a problem-solving task, for example, may yield the same final result as a more systematized strategy, even though these approaches reflect different underlying processes. Furthermore, the reliance upon either of these processes may have very different implications for patients in terms of their effectiveness in everyday functioning and in their ability to cope with novel situations. This approach to neuropsychological assessment is perhaps nowhere better illustrated than in the Boston Process Approach to clinical neuropsychology (see Milberg, Hebben, & Kaplan, 1996, for an overview) which incorporates an examination of the process or manner in which tasks are performed rather than relying upon final or summary scores alone. In some approaches to neuropsychological assessment, there is an emphasis on specific test scores, with less attention paid to how scores are achieved, the cognitive functions underlying those scores, the relative preservation of component functions that may be indicated, and the manner in which those scores may relate to the patient's functioning in everyday life situations.

As noted, many clinical neuropsychologists implement aspects of flexible and standard, quantitative and qualitative approaches to assessment in practice, and these should not be viewed as mutually exclusive. Perhaps more important is the approach to test interpretation and performance analysis, which represents a multidimensional process. As noted earlier, the dimensions of level and pattern of performance on neuropsychological tests are very important to consider. In some cases, the level of performance may suggest normal functioning, while the pattern of test results suggests the presence of an abnormal process. Along these lines, it is important to keep in mind that scores in the "normal" or "average" range may reflect impairment in some individuals compared to their premorbid or baseline level of functioning. For example, the average IQ and memory scores in the previously high-functioning college professor who sustained a traumatic brain injury (TBI) may represent a significant decline in functioning, even though the obtained scores remain within the "normal" range (e.g., see Naugle, Cullum, & Bigler, 1990). Furthermore, if the patient achieves a good score on a particular test, but does so in an abnormal manner, this, too, may reflect altered mental function. Careful consideration of these factors, along with the pattern of test results and the degree to which the findings are consistent with deficits commonly seen in TBI, are essential in arriving at a correct diagnosis. Furthermore, the quantitative and qualitative information gained through a comprehensive neuropsychological examination may be very important in providing appropriate feedback and making realistic recommendations to the patient. Thus, as with the combination of standard and flexible test batteries, utilization of quantitative as well as qualitative data from the neuropsychological evaluation can be of extreme importance.

4.11.2.5 Other Issues in Test Interpretation

Regardless of a clinician's primary approach to neuropsychological assessment, the determination of what tests are to be given to each patient requires forethought and planning, and may vary depending upon the patient's age, level of education, socioeconomic status and ethnic background, and clinical presentation. For example, the neuropsychological evaluation of a retired physician following a mild brain injury would require the administration of a different set of measures than an 87-year-old laborer referred for diagnostic confirmation of

Alzheimer's disease who is known to have at least a 10-year history of progressive decline. As a more extreme example, the workup of an elderly individual with three years of education and limited English speaking abilities would require careful test selection to avoid measures with high cultural and educational biases.

4.11.2.5.1 Test cutoff scores

The use of "cutoff" or "cut" scores is another issue that merits comment, because this comes up frequently in clinical practice and often serves as a topic of debate. The cutoff score is based on the notion that most normal individuals tend to perform above a certain level on a given test, while most brain-injured individuals score below that level. From a statistical perspective, the notion of cutoff scores holds some merit, since many test results are normally distributed, and depending upon sensitivity and specificity qualities desired, cut points in a distribution can be set in order to maximize one or the other or both. This approach will produce definable true-positive and false-positive hit rates for groups, although statistical inferences may differ when applied to any given individual case. As a result, definitions of what constitutes "impairment" vs. "normalcy" may vary depending upon a variety of factors such as age and education, to take two of the more extensively studied demographic variables. Different cutoff scores for impairment would be needed to adjust for the effects of age on a given test, since age has a significant effect on so many cognitive measures. Using the original cutoff score of 90 seconds for the Trail Making Test—Part B, for example, would result in many healthy elderly individuals being misclassified as "impaired," when in fact their performances on this test may fall well within normal limits or even above average for their age. Similar considerations must be made with respect to different educational levels and estimated premorbid intellectual functioning, which can have a profound impact on the interpretation of certain neuropsychological test scores.

4.11.2.5.2 T-scores

Heaton, Grant, and Matthews (1991) provide normative reference values (*t* scores) for an extensive battery of tests that includes the HRB. This work, and the accompanying supplement for the WAIS-R (Heaton, 1992), represents a monumental contribution to the field by providing age-, education-, and where appropriate, gender-adjusted standard scores for an array of neuropsychological tests. The use of demographically-corrected *t* scores (derived from the same normative population) places all test results on the same metric (mean = 50, SD = 10, with lower scores reflecting poorer performances), thereby allowing for ready comparisons across areas of cognitive functioning. For example, questions such as, "Is memory more impaired than expected given an individual's background and overall level of functioning?" can be addressed through the use of such standardized scores. Also, the effects of age and education on specific test results can be more readily appreciated, even when such factors may be thought to have little influence on a given task. For example, if it takes a 30 year old female with a high school education 90 seconds to complete Trails B, the corresponding *t* score is 38, which reflects a mild impairment, just over one standard deviation below average. If that individual were 75 years old, however, that same level of performance would fall in the above-average range (*t* score = 56).

The use of *t* scores allows for an individual's performance on specific tests to be compared with results from healthy groups of subjects of similar gender, age, and educational backgrounds rather than relying upon strict cutoff scores in order to help determine the degree of normality–abnormality of findings. If enough scores fall below expectation and/or form a consistent pattern of deficits, the likelihood of cerebral dysfunction is increased.

Given the error variance of any behavioral measure, *t* scores, like IQ or other standard scores, should not be used as rigid neurobehavioral markers that are absolute or "true" scores, but rather as interpretive guidelines to assist in evaluating levels and patterns of performance in a particular case. Furthermore, caution must be used in the strict application of interpretive scores and guidelines derived from normal populations to cases of brain-injured individuals (e.g., see Reitan & Wolfson, 1996). Another potential risk of over-reliance upon standardized scores in neuropsychological interpretation is that it can potentially give the (particularly inexperienced) clinician a false sense of security, when in fact, it is the neuropsychologist's training, knowledge base, experience, and skill in interpreting various aspects of test performance and behavior that result in valid neuropsychological conclusions regarding cerebral integrity.

4.11.2.6 Computer Interpretation of Neuropsychological Assessment Results

Computer-derived interpretive programs have been developed for several standard test batteries (e.g., HRB, Luria–Nebraska Neuropsychological Battery). While such programs attempt to make general statements regarding the likelihood and even pattern of cerebral dysfunction based upon normative and neuropathological data and "typical" profiles, these programs may lend a false sense of interpretive security to those with more limited training and experience in clinical neuropsychology. While certain features of some such programs are arguably useful in certain situations (e.g., rapid scoring and normative referencing of results), they must be used with caution. Because brain damage affects individuals in different ways (i.e., a lesion in a specific location may produce different symptoms across individual patients depending upon a host of interindividual neuroanatomic, neuropathologic, genetic, experiential, and personality factors), any blanket statements about the nature of neurobehavioral disturbance in an individual must be examined carefully within the context of the patient in question. Particular care must be used when computer interpretations yield purported localization indices, since this process requires knowledge of underlying neuroanatomical systems, neuropsychiatric disorders, and individual neurobehavioral variations in order to optimize diagnostic accuracy. Attempts to distill numerically the complex process of clinically weighing various test scores, combinations of results, and qualitative performance features into "focal" interpretive patterns is a most challenging prospect, indeed, and erroneous interpretations can be rendered through over-reliance upon some of the available test interpretation programs.

4.11.2.7 Cognitive Screening

In keeping with the current managed-care *Zeitgeist*, neuropsychological evaluations should be appropriately detailed and comprehensive, while at the same time designed to provide the maximum amount of information in a time- and cost-efficient manner. It should be kept in mind, however, that brief cognitive assessments should not be carried out at the expense of thoroughness. In some cases, a brief examination may be adequate to address referral questions, as in the case of documenting cognitive impairment in a patient with severe dementia. A thorough examination of such a patient might be accomplished readily through the use of cognitive screening tools, and in fact, the administration of an eight- or 10-hour battery of measures in such a case might not yield any more diagnostic or clinically useful information than a brief assessment. However, evaluations that are overly brief may be insensitive to mild or even more significant cognitive deficits. Take, for example, the ever-popular MMSE, which is arguably the most widely used cognitive screening tool and provides a very brief assessment of orientation, simple language, and recent memory skills. Whereas such instruments have utility in quantifying gross level of impairment when more severe brain dysfunction exists, scores that fall in the "normal" range on this test do not rule out cognitive abnormality. That is, simple screening measures such as the MMSE tend to have a high false-negative rate (i.e., identifying patients as being intact, when in fact, they are not). For example, diagnostic error rates using traditional cutoff scores on the MMSE (i.e., <24/30) can be around 15% even among patients with a diagnosis of possible or probable Alzheimer's disease (Cullum & Rosenberg, 1998); in less impaired populations, the false-negative rate likely will be higher. Although the use of cognitive screening tools like the MMSE is preferable to a more idiosyncratic and non-standardized clinical mental status evaluation, the limitations of any brief cognitive screening tool must be kept carefully in mind. Along these lines, as with other measures of cognitive function, the use of cutoff or specific reference scores on such tests must be carefully considered in light of the individual patient's background. Demographic factors often influence cognitive tests, and appropriate norms should be used even in the case of brief screening tools (e.g., see Crum, Anthony, Bassett, & Folstein, 1993 for age- and education-corrected MMSE scores).

4.11.3 METHODS OF NEUROPSYCHOLOGY

Neuropsychological assessment provides the most sensitive and comprehensive means by which brain function and cognition can be assessed given our current state of technology. The techniques are used widely in various settings across many patient populations, and are recognized by the American Academy of Neurology as accepted diagnostic procedures (Report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology, 1996). Neuropsychologists often serve as consultants to neurologists, neurosurgeons, psychiatrists, clinical psychologists, and other medical and health professionals.

Neuropsychological tests are the means by which neurobehavioral samples are elicited, and specific test scores represent summary statements about observed behaviors and cognitive capabilities. Obtaining valid behavioral samples is critical, as is a thorough knowledge of the range of responses made by patients with and without various neurobehavioral disorders. As noted in neuropsychology training programs, neuropsychological tests are no better than the clinician interpreting them. Thus, the best tests in poor or inadequately trained hands may fail to yield the correct neurobehavioral conclusions, and it is the clinician that is the instrument of evaluation—not the tests alone. Appropriate specialized training in neuropsychology is essential to conduct detailed neuropsychological evaluations beyond a cognitive screening level, and this is the topic of a section later in this chapter.

4.11.3.1 Clinical Interview and Background Information

Prior to a discussion of individual cognitive domains and specific representative measures, an overview of some of the other information that is essential to the neuropsychological examination is in order. In addition to a formal examination of mental functions, information pertaining to the patient's history, presenting complaint, and overall functional status is essential. In order to interpret results from any neurobehavioral task, an understanding of the behavioral geography of the brain and the underlying cerebrocortical systems is critical. It should be kept in mind that many cognitive processes represent inter-related phenomena and that individual tasks seldom assess highly specific skills or involve circumscribed cerebral areas in isolation. Second, background variables of the patient, including their age, level of education, SES, and cultural background, must be kept in mind while asking them to perform various tasks. Third, it should be kept in mind that the clinician interpreting the test data is the key to a good neuropsychological evaluation. Even the most sensitive tests in the hands of the inadequately trained clinician may yield erroneous conclusions. This is particularly true in cases of subtle behavioral abnormalities that may only be elicited through the use of specific cognitive tasks or detected via the careful and experienced observation of characteristic symptoms or behavior patterns. Table 1 provides an overview of much of the information that should be collected as part of the clinical interview within the context of the typical neuropsychological evaluation. Such data form a basis for the selection of assessment procedures as well as interpretation and integration of findings.

After obtaining this information, the selection of neuropsychological tests can be done, with particular areas of interest being stressed depending upon the referral question, nature of the disorder(s) under consideration, and patient complaints and presentation. In many settings, neuropsychological tests are administered by highly trained psychometrists or technicians. These individuals are responsible for standardized test administration and scoring under the supervision of the clinical neuropsychologist. This is a recognized standard practice in the field that is endorsed and/or utilized by a majority of neuropsychologists (Sweet & Moberg, 1990).

Table 1 Cognitive domains typically assessed by the comprehensive neuropsychological evaluation.

1	Global cognitive/intellectual functioning
2	Academic achievement
3	Executive functioning/problem-solving
4	Language
5	Visuospatial processing
6	Attention/concentration
7	Learning and memory
8	Psychomotor functions
9	Sensory perceptual abilities
10	Psychological functioning

4.11.3.2 Neuropsychological Measurement of Brain Function

The comprehensive neuropsychological evaluation includes the administration of tests that comprise multiple cognitive domains. Although the specific tests selected by individual neuropsychologists may vary, the domains listed in Table 2 are commonly represented.

Excellent descriptions and reviews of the most frequently used cognitive measures (as well as normative data for some tests) can be found in Lezak (1995) and Spreen and Strauss (1998), and the reader is encouraged to consult these comprehensive reference sources. Table 3 presents some of the more commonly used tests to assess these cognitive domains. It should also be noted that there may be significant overlap between some of the listed tests, and across domains. The tests are listed for illustrative purposes and are not intended to provide an exhaustive list or to reflect a prototypical clinical neuropsychological test battery.

The question sometimes arises as to why a neuropsychological evaluation cannot be extremely focused, that is, "Why not administer a single test of memory to a patient if that is the only presenting complaint?" The answer obviously is that by using only one test or assessing only one cognitive domain, the clinician might completely overlook the actual cause of the patient's reported difficulties. For example, an individual presenting for memory disturbance may actually have primary difficulties in attention and concentration which preclude their ability to efficiently encode new material. When that individual attempts to recall information at

Table 2 Common neuropsychological measures.

Representative measures	*Functions assessed*
Intellectual	
Wechsler Adult Intelligence Scale-3 (WAIS-III) and Wechsler Adult Intelligence Scale-Revised (WAIS-R)	Global cognitive capacity/ Intelligence
National Adult Reading Test-Revised (NART-R)	Premorbid IQ estimation
Global cognitive	
Dementia Rating Scale (DRS)	Presence and level of dementia
Mini-Mental State Examination (MMSE)	Gross cognitive screening
Academic achievement	
Wide Range Achievement Test-3 (WRAT-3)	Reading, spelling, math
Pearowstart Individual Achievement Test-Revised (PIAT-R)	Reading, spelling, math
Wechsler Individual Achievement Test (WIAT)	Basic academic skills
Executive function and problem-solving	
Wisconsin Card Sorting Test (WCST)	Cognitive flexibility/problem-solving
Category Test	Abstraction and reasoning
California Sorting Test (CST)	Cognitive flexibility/idea generation
Similarities (WAIS-III, WAIS-R)	Abstraction
Trail Making Test (Part B)	Mental sequencing/flexibility
Raven's Matrices (standard, colored, advanced)	Nonverbal reasoning
Language	
Vocabulary (WAIS-R)	Word knowledge
Boston Naming Test (BNT)	Confrontation naming
Word fluency; Controlled Oral Word Association	Verbal fluency
Token Test	Comprehension
Boston Diagnostic Aphasia Examination (BDAE)	Overall language function
Aphasia Screening Test	Language screening
Visuospatial	
Block Design (WAIS-R)	Visuoconstructional ability
Clock drawings (command and copy)	Graphomotor construction
Cross drawings (command and copy)	Graphomotor construction
Rey–Osterrieth Complex Figure (copy)	Graphomotor construction/planning
Hooper Visual Organization Test (HVOT)	Visuoperceptual integration
Object Assembly (WAIS-R)	Visuospatial integration
Line bisection, Visual cancellation tests	Hemispatial inattention
Ruff Figural Fluency Test	Nonverbal fluency
Attention/Concentration	
Digit Span forward (WAIS)	Simple attention
Digit Vigilance (number cancellation)	Sustained concentration and attention
Paced Auditory Serial Addition Test (PASAT)	Auditory concent/processing speed
Digit Symbol (WAIS) or Symbol Digit Modalities Test	Visual attention/psychomotor speed
Trail Making Test (Part A)	Visual tracking/psychomotor speed
Continuous Performance Test (various versions)	Sustained vigilance and reaction time
Visual Sustained Attention Test (VSAT)	Sustained concentration and attention
Learning and memory	
Wechsler Memory Scale-3 (WMS-III) and Wechsler Memory Scale-Revised (WMS-R)	Global memory function
California Verbal Learning Test (CVLT)	Verbal learning and memory
Logical Memory (WMS-III, WMS-R)	Verbal memory
Visual Reproduction (WMS-III, WMS-R)	Nonverbal memory
Rey–Osterrieth Complex Figure (recall)	Complex nonverbal memory
Hopkins Verbal Learning Test	Brief measure of verbal memory
Benton Visual Retention Test	Nonverbal memory
Warrington Recognition Memory Test	Verbal/nonverbal recog. memory
Rey Auditory Verbal Learning Test	Verbal learning and memory
Buschke Selective Reminding Test	Verbal learning and memory
Motor and sensory	
Finger Tapping Test	Fine motor speed
Hand Dynamometer	Grip strength
Grooved Pegboard	Fine motor dexterity
Luria three-step hand sequence	Coordinated/integrated sequencing
Sensory-Perceptual Examination (Reitan–Klove)	Sensory and perceptual skills

Table 3 Information to be collected from the history and behavioral observations.

History of symptoms
- Description of present illness and specific symptoms (e.g., Why is patient being evaluated?)
- Nature of onset (e.g., insidious vs. acute; are symptoms new or a recurrence?)
- Duration
- Course of symptoms
- Associated behavioral or personality/emotional changes

Past medical history
- Previous neurological disease
- Previous psychiatric disease (psychiatric treatment, known diagnoses, etc.)
- Significant head trauma (details: presence and length of LOC/coma; PTA—assess)
- Seizures (circumstances of onset, frequency, characterization of seizures)
- Other medical illnesses requiring hospitalization
- Toxic Exposure (may relate to work history)

Birth and developmental history
- Birth complications
- Developmental delays (motor, language, intellectual)

Social history
- Abnormalities in behavior past and present
- History of and current family and peer interactions

Educational history
- Highest grade attained/ degrees awarded
- Specific problems learning
- Problems in school (e.g., truancy, being expelled, etc.)
- Typical grades in school (e.g., below average, average, above average)
- Best and worst subjects in school
- Reasons for termination of education (if relevant; also, if not HS, did get GED?)

Vocational history
- Present occupational status (if retired, what was last position)
- Length of current job
- Nature of responsibilities
- Types of previous jobs
- Frequency of job changes
- Recent difficulties with work (self-report, work appraisals, raises, etc.)

Substance use history
- Duration, frequency, and amounts of typical alcohol intake
- Use of other drugs
- Use of prescription medications (list current medications)

Family history
- Neurologic disease in family (especially parents, siblings)
- Psychiatric disease in family
- Familial predilection for diseases (e.g., learning disabilities, dementia, epilepsy, etc.)
- Cause and age of death of parents and siblings

Psychiatric symptoms
- Unusual or bizarre behavior
- Attention/concentration problems—distractibility
- Problems with social judgment
- Depression
- Anxiety
- Paranoid ideation/suspiciousness
- Hallucinations
- Delusions
- Tangentiality, looseness of associations

General appearance
- Appropriateness of appearance for age
- Posture (examine for asymmetries)
- Facial expression
- Eye contact
- Personal cleanliness, grooming, dress

Mood
- Range and appropriateness of affect, responsiveness to conversation/interview
- Depression
- Apathy
- Lability

Table 3 (continued)

- Mania or hypomanic symptoms

Behavioral
- Cooperativeness with examiner
- Anxiety
- Suspiciousness
- Anger
- Insight
- Response to interview

Motor
- General activity level
- Abnormal posturing, movements, tremors, etc.
- Gait (broad-based, shuffling, unsteady, symmetry of movement)
- Handedness (and familial history thereof, particularly if left-handed)

Speech
- Rate
- Volume
- Modulation
- Expression
- Dysarthria

a later time, they fail, thereby producing what subjectively seems like a deficit in memory. In actuality, their problem may not be at the retrieval or recall stage, but rather, at earlier stages of information processing. Similarly, a patient with aphasia may present with word-finding difficulty that might also mimic a memory impairment if the individual were not thoroughly evaluated. Some patients with frontal lobe damage demonstrate inefficient encoding secondary to organizational deficits, when in fact their ability to recall learned material may be normal.

The following section discusses the major cognitive domains typically assessed by the comprehensive neuropsychological evaluation, including an overview of some common representative measures from each domain. Each section begins with a clinical overview of the area to be examined and includes a brief discussion of relevant, less structured or "bedside" clinical examination/observation procedures prior to a presentation of specific psychometric assessment tools.

4.11.4 PRINCIPAL COGNITIVE DOMAINS FOR ASSESSMENT

4.11.4.1 Global Cognitive/Intellectual Functioning

The concept of intelligence has a long history and has been the topic of much discussion and controversy since the early 1900s. Various definitions of intelligence have been posited (Sternberg, 1997), and it is clear that intelligence is a multidimensional construct that is made up of many types of abilities that are demonstrated by each of us to varying degrees. Despite ongoing debate regarding the use of IQ measures, the concept of global intellectual capacity has utility within the context of assessing cognitive functioning and adaptive ability as it relates to brain function.

From a clinical bedside perspective, the clinician must rely upon the patient's educational and vocational history, in addition to their overall presentation style, use of language (when possible), and performance during various cognitive tasks to estimate a gross level of intellectual functioning. Next, one must begin to evaluate whether there seems to be evidence of gross intellectual decline based on their current presentation. Ideally, premorbid IQ and other cognitive test scores would be available for direct comparison, but this is rarely the case. Thus, detailed examination of this issue requires formal psychometric assessment, and based on specific cognitive test results and patterns of test scores, indices of current intellectual functioning as well as estimates of premorbid intelligence can be derived (Franzen, Burgess, & Smith-Seemiller, 1998).

The most commonly used intellectual assessment tools for adults are the Wechsler Intelligence Scales. In addition to the information provided by the various component subtests of the Wechsler Scales, some assessment of an individual's global level of cognitive capacity is important in establishing an interpretive background for other specific test results. For example, knowing that a patient has a Full-Scale IQ (FSIQ) score in the borderline range can be very useful in accurately interpreting their low average to borderline performance on memory tests. Although some variability across cognitive skills is commonly seen within individuals, higher intellectual levels tend to be associated with more advanced skills in various domains.

Thus, the 75-year-old retiree with eight years of formal education who obtains an FSIQ of 120 would be expected to perform at a higher level on memory or attention/concentration measures than the elderly individual with a similar educational background, but an IQ in the low average range.

One of the limitations of intellectual assessment that is worth noting is the use of global IQ scores in depicting an individual's cognitive capabilities. An FSIQ of 100 can be arrived at in various ways, for example, by achieving an very high Verbal IQ and low Performance IQ score, or vice-versa. On the WAIS-R, note that each of the following sets of VIQ/PIQ scores result in an FSIQ of 100 for a 30-year-old: (i) VIQ = 121, PIQ = 79; (ii) VIQ = 80, PIQ = 138; (iii) VIQ = 100, PIQ = 101. Also, some subtest scaled scores may be very high and offset lower ones, resulting in an "average" overall IQ score. These examples represent significantly different cognitive processing styles and differential ability patterns, although these distinctions would be lost if there is an over-reliance upon global IQ scores.

From a neuropsychological perspective, intellectual tests such as the WAIS-R and WAIS-III can be quite useful in describing cognitive strengths and weaknesses and eliciting relevant neurobehavioral samples, even though these tests were not originally designed for assessment of cognitive dysfunction. However, many of the changes in the WAIS-R reflected in the WAIS-III, in fact, were influenced by neuropsychological principles, and the WAIS-III includes several new subtests that attempt to provide a more detailed exploration of cognitive abilities beyond "IQ" or "g" alone. Whereas intellectual tests tend to be less sensitive to cerebral dysfunction than many specialized neuropsychological measures of specific abilities, the relative sensitivity of some subtests to cerebral dysfunction have proven useful in detecting gross cognitive decline in some cases. For example, the Vocabulary subtest of the WAIS-R historically has been known as one of the tests that is least sensitive to acquired cerebral dysfunction. This subtest relies upon highly crystallized and overlearned knowledge, and the ability to define familiar words tends to be a function that is relatively less affected by acquired brain damage than many other tasks that require novel learning or reasoning. In contrast, the Digit Symbol subtest of the WAIS-R, which requires rapid psychomotor speed, new learning, and attention, is one of the more sensitive subtests to cerebral dysfunction. Knowledge regarding which subtests are more or less sensitive to brain injury, educational background, age, gender, and so on, is essential in making inferences about cerebral dysfunction (see Heaton, Ryan, Grant, & Matthews, 1996). Pattern analysis of the Wechsler scales can thus be quite useful in the assessment of brain damage, as the subtests are differentially susceptible to the effects of acquired brain injury and can be further impacted depending upon the nature of the disorder and/or location of primary cerebrocortical involvement. These tests are described now in detail.

(i) *Wechsler scales*. (a) Wechsler Adult Intelligence Scale-Revised. The Wechsler Adult Intelligence Scale-Revised (WAIS-R; Wechsler, 1981) is the most popular measure of intellectual functioning in adults, and has enjoyed widespread use since its introduction in 1981. A plethora of studies using the WAIS-R or its components has been published in the neuropsychological literature, and a great deal has been learned about its utility as a neuropsychological tool. This is underscored by the development and publication of the WAIS-R as a neuropsychological instrument (WAIS-R-NI; Kaplan, Fein, Morris, & Delis, 1991). This modification of the WAIS-R reflects the application of specific neuropsychological principles and procedures to the administration of the WAIS-R. For example, in individuals with difficulty responding to open-ended questions or those having initiation difficulties, the Information subtest of the WAIS-R-NI includes a provision for multiple choice responding. Some of the timed subtests include extended time limits for those with motoric slowing to permit a more valid assessment of visuoconstructional skills apart from the effects of motor dysfunction.

In settings where an overall estimate of intellectual functioning is desired, various short forms of the WAIS-R have been developed. One very brief example is the combination of Vocabulary and Block Design in the estimation of FSIQ (Brooker & Cyr, 1986; Silverstein, 1982). Such brief forms and lengthier procedures (e.g., Adams, Smigielski, & Jenkins, 1984) have shown reasonable correlations with the complete WAIS-R, and these estimates may be adequate in some situations. For example, in a case of head injury wherein the focus is upon more subtle difficulties with attention/concentration and memory, less of an emphasis may be placed on global intellectual status, particularly when there are no questions of a decline in this area. In selecting the shortened version of any test such as the WAIS-R, clinicians must rely upon experience with a large number of cases and with appropriately supportive literature. Among the individual subtests that show the strongest correlations with overall FSIQ scores is the Vocabulary subtest ($r = 0.81$), followed by Information ($r = 0.81$). At the other end of the spectrum lies Digit Symbol, which, along with Object Assembly, shows a correlation of 0.57 with FSIQ. In general, the five Performance subtests, which rely more upon novel thinking and "fluid" cognitive skills, tend to be more sensitive to cerebral dysfunction than the more crystallized abilities tapped by the six Verbal subtests. Because the various subtests of the WAIS-R assess a variety of cognitive abilities, some of these will be discussed in more detail under specific cognitive domains.

(b) Wechsler Adult Intelligence Scale-III. The WAIS-III is a newly revised version of the Wechsler Adult Intelligence Scale (WAIS-III; Wechsler, 1997a). It contains a variety of changes and additional subtests, and some previously familiar measures have been dropped or are now optional. The addition of a matrix reasoning task and measures of sustained concentration and working memory promise to provide a more well-rounded evaluation of global cognitive functioning and may enhance the test's utility in the context of the neuropsychological evaluation. Most of the familiar subtests remain, although these have been updated for the 1990s, with improved norms. Many subtests that include scenes for visual material now are presented in color, with larger figures and a more representative depiction of our multicultural society. As a quick review of the test evaluators and consultants will indicate, there is a decidedly more neuropsychological flair to the WAIS-III. As we have learned more about brain–behavior relationships and the effects of acquired cerebral dysfunction on intellectual functioning, test developers felt it important to incorporate aspects of this knowledge into the current test design. Table 4 lists the subtests for the WAIS-III.

Table 4 WAIS-III subtests.

Vocabulary	Picture Completion
Similarities	Digit Symbol–Coding
Arithmetic	Block Design
Digit Span	Matrix Reasoning
Information	Picture Arrangement
Comprehension	Symbol Search
Letter–Number Sequencing	Object Assembly

As reported in the WAIS-III technical manual (Wechsler, 1997a), correlations involving VIQ, PIQ, and FSIQ scores between the WAIS-III and WAIS-R are high (0.94, 0.86, and 0.93, respectively). WAIS-III VIQ, PIQ, and FSIQ scores were found to be an average of 1.2, 4.8, and 2.9 points lower than the corresponding values on the WAIS-R. Obviously, given the recent release of this test, many studies of its neuropsychological utility and psychometric relationships to other neuropsychological measures will be forthcoming.

(c) The Wechsler scales and patterns in neurological populations: VIQ–PIQ Differences. Despite the utility of instruments like the Wechsler scales in neuropsychological evaluations, appropriate interpretation of scores and patterns of scores in cases of brain dysfunction requires extensive training in neuropsychology and familiarity with a broad range of neuropathological, neuropsychiatric, and normal conditions. For example, deficits on PIQ subtests are often discussed in association with right hemisphere dysfunction. Whereas this may hold true in many cases, decreased nonverbal test scores may occur for a variety of reasons (e.g., psychomotor slowing on timed tasks, greater sensitivity to acquired brain injury than most of the VIQ tasks). The following cases serve to illustrate this point.

First it should be noted that all three cases depict at least a 22-point difference between VIQ and PIQ scores, although there is obviously some variability across the profiles in terms of specific scaled scores. One initial impression might be that all three cases likely represent some sort of acquired brain injury, as 20-point differences between IQ indices are rare in the general population. A second level of interpretation, based in part on the clinical lore associated with the test, might include an inference about lateralization, that is, all three cases might be suggestive of greater impairment of right hemisphere functions, given the large VIQ–PIQ differences and relative deficits on the "nonverbal" subtests. As alluded to earlier, knowledge that a variety of factors may result in decreased PIQ scores can provide the clinician with information that is essential in neurodiagnostic situations.

Case 1 is an engineer in his 40s who sustained a right hemisphere stroke. CT findings (Figure 3) depict a hemorrhage deep in the right hemisphere that included intraventricular bleeding.

His WAIS-R profile of decreased nonverbal abilities and a 22-point VIQ–PIQ discrepancy is what is often associated with a "classic" pattern of right hemisphere dysfunction (see Figure 4). Whereas this holds true for this particular individual, Cases 2 and 3 illustrate that simplistic interpretations or overgeneralizations can lead to erroneous conclusions.

Case 2 is a 50-year-old nurse with a history of stroke four months prior to evaluation. MRI results (Figure 5) revealed a chronic egg-sized hemorrhage involving the left internal capsule and basal ganglia.

Her primary presenting symptoms included mild right-sided hemiparesis and mild difficulties with verbal fluency and word finding. Much of the decrease in PIQ subtest scores (Figure 6)

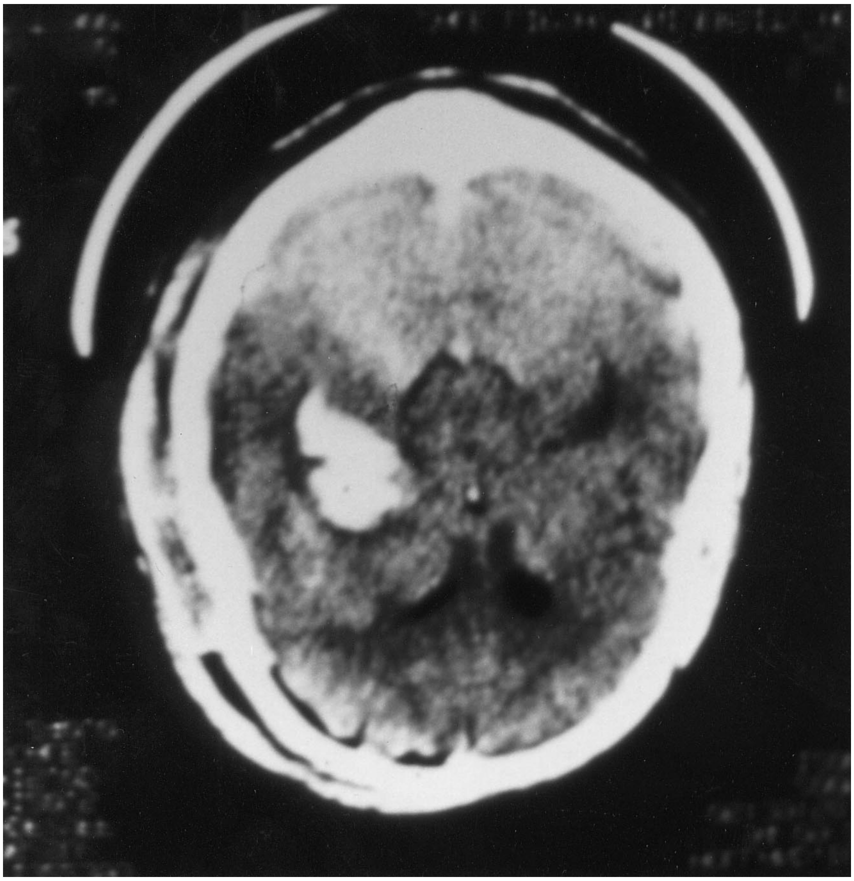

Figure 3 CT from Case #1 showing right hemisphere infarct.

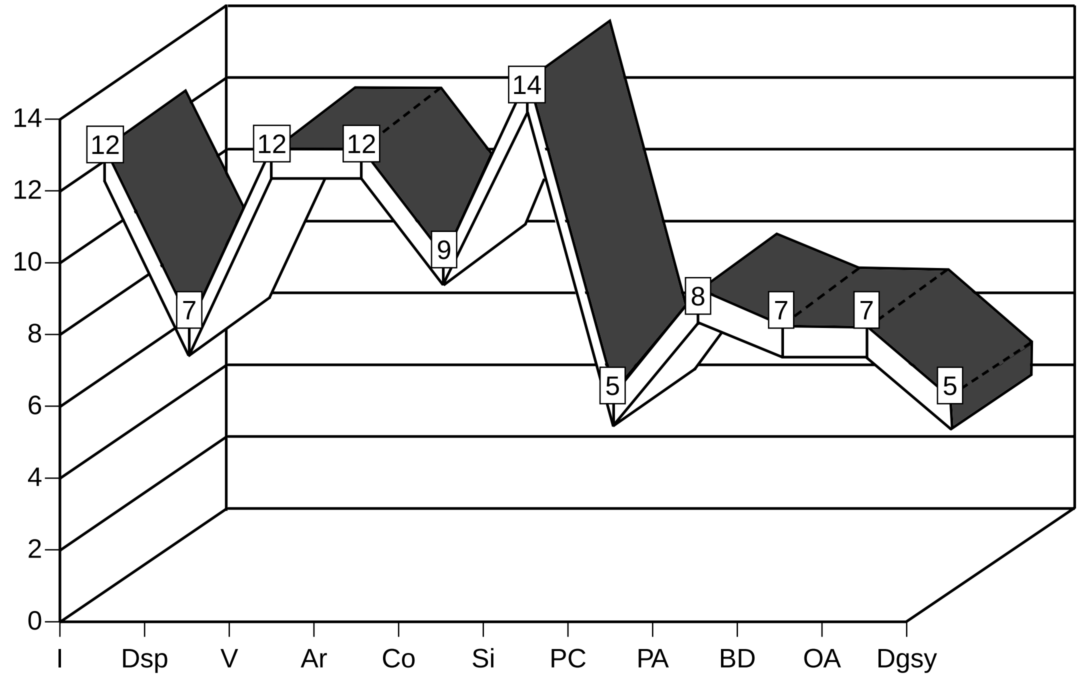

Figure 4 WAIS-R scaled scores from case #1. VIQ = 108, PIQ = 86, FSIQ = 98.

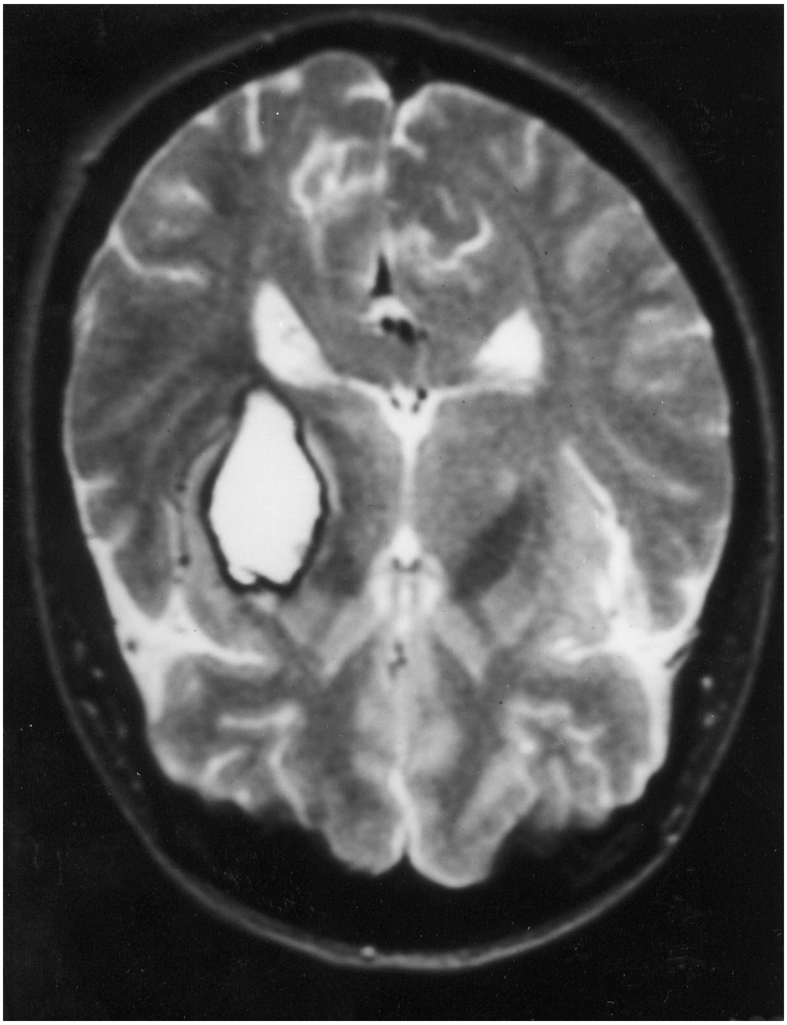

Figure 5 MRI showing left basal ganglia/internal capsule hemorrhage in case #2 (note that left is depicted on the right).

was felt to be related to the patient's hemiparesis and having to perform some tasks with her nondominant left hand. However, the relative sensitivity of nonverbal vs. verbal WAIS-R subtests to any type of acquired brain damage should be kept in mind, and in fact, additional time allowances on some of the PIQ subtests (e.g., Block Design) still resulted in evidence of cognitive impairment; thus, psychomotor factors alone could not completely explain the patient's difficulties in performing these tasks.

Case 3 results are from a 40-year-old long-term alcoholic who showed evidence of alcohol-related dementia. Axial MRI results (Figure 7) depict generalized sulcal widening and ventricular dilation.

The patient demonstrated generalized neuropsychological deficits, with particular difficulties in visuospatial abilities (see Figure 8). Results such as this are not uncommon in cases of extensive and long-term (i.e., 10+ years) alcohol abuse, and this pattern of findings on the WAIS-R was amply supported by the patient's impaired performances on other visuoconstructional tasks.

(d) WAIS subtest "scatter." The issue of "scatter" among WAIS-R subtest scaled scores represents another area of clinical lore that merits comment within the context of assessing patients with known or suspected cerebral dysfunction. It has been observed by some that, in cases of brain damage, there tends to be a greater than average range of scores from highest to lowest across subtests. This represents a complex issue, since most individuals with or without brain damage have relative cognitive strengths and weaknesses, and as noted, the subtests differ with respect to their individual sensitivity to acquired cerebral dysfunction.

Finally, what constitutes clinically "significant" scatter across Wechsler subtest scores also

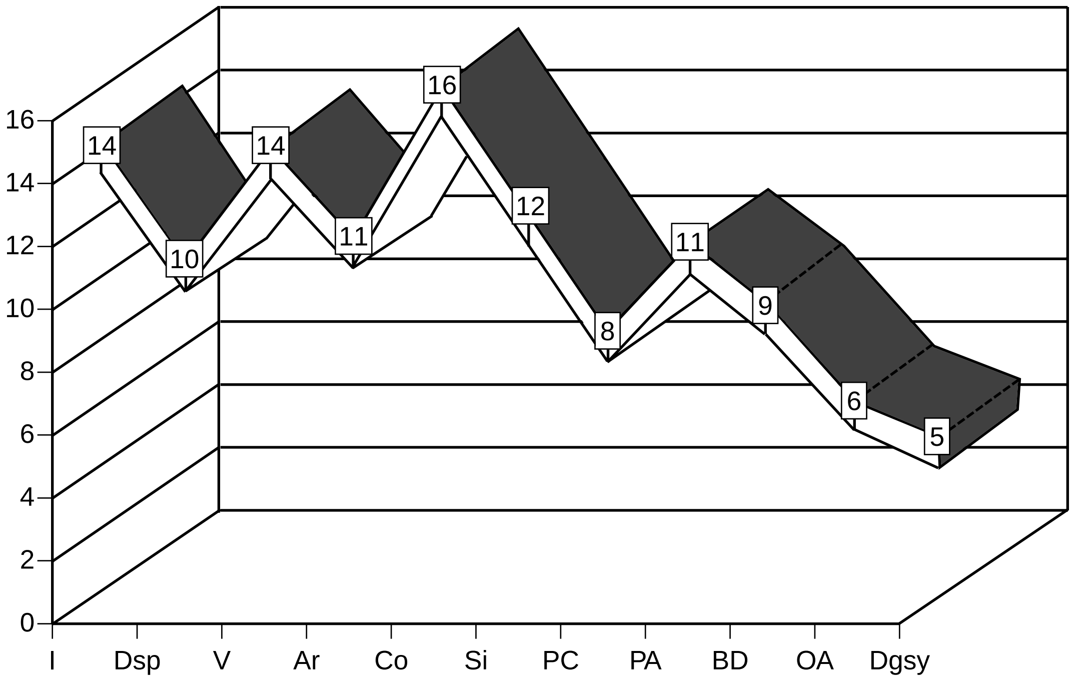

Figure 6 WAIS-R scaled scores from case #2. VIQ = 121, PQ = 101, FSIQ = 112.

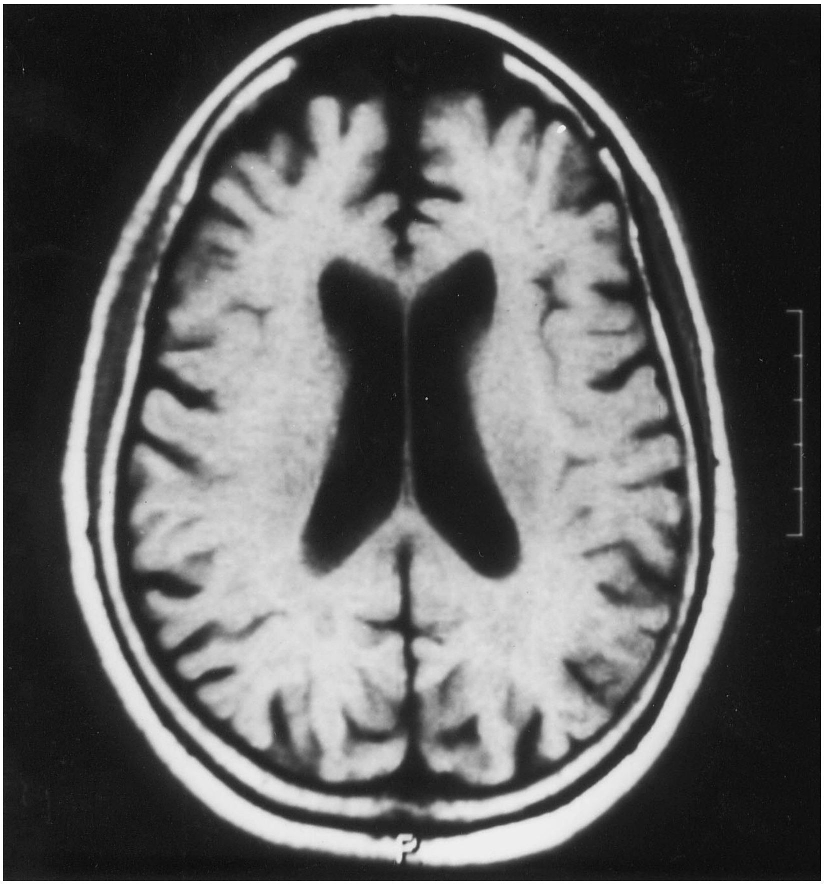

Figure 7 MRI results from case #3 showing generalized atrophy.

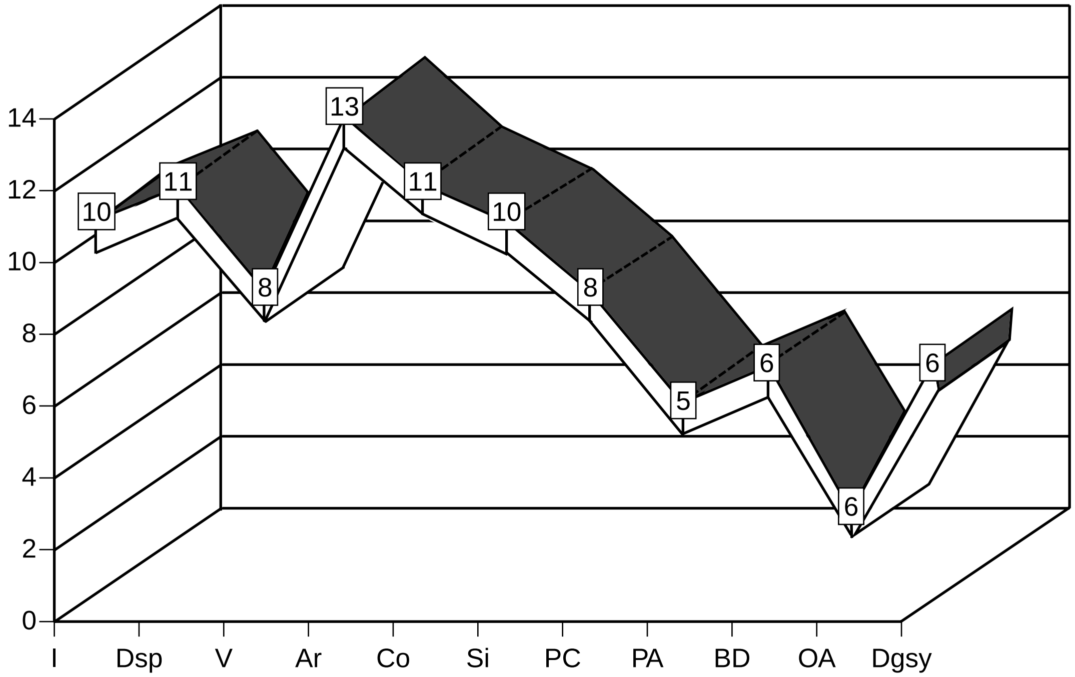

Figure 8 WAIS-R scaled scores from case #3. VIQ = 103, PQ = 78, FSIQ = 90.

merits careful review. In his APA Presidential address, Matarazzo (1990) provides data that clearly calls to question the notion of the relevance of "scatter." For example, a table is presented (p. 1010) that was derived from previous work (Matarazzo & Prifitera, 1989) which includes the percentage of cases from the WAIS-R standardization sample that demonstrate various levels of scatter (the difference between highest and lowest of the 11 subtest scaled scores). While extreme score differences of greater than 10 points were rare (i.e., seen in less than 5% of the 1880 standardization sample subjects), discrepancies of 10 points were seen in approximately 9% of the sample, while differences of seven points occurred in almost half of the sample, and roughly 86% showed a difference of five points. Thus, it should be kept in mind that "scatter" among WAIS subtest scaled scores is commonly seen in non-neurological populations. With these numbers in mind, the issue of the neurological significance of scatter among Wechsler scaled scores should be considered cautiously.

(ii) *Ravens Progressive Matrices*. This series of tests includes the Colored (Raven, 1995), Standard (Raven, 1996), and Advanced (Raven, 1994) Progressive Matrices, providing different levels of assessment of nonverbal reasoning. In the Colored Matrices, subjects are shown a stimulus array at the top of a booklet, with one small piece cut away. Below this, six small pieces corresponding to the outline of the missing piece are presented; however, each typically has a different pattern depicted. The task is to select the piece that best completes the stimulus array. The Colored matrices are particularly well suited for children and impaired elderly, and the Advanced matrices are most appropriate for high functioning individuals when an assessment of nonverbal reasoning is desired. IQ equivalent scores can be derived from the matrices, and their nonverbal nature (particularly the Colored version) allows for those with language impairments or limited fluency in English to apprehend the nature of the task quite readily in many cases.

(iii) *National Adult Reading Test-Revised (NART-R)*. This is a measure of estimated premorbid intellectual functioning (Blair & Spreen, 1989) as derived from the original NART (Nelson, 1982; Nelson & O'Connell, 1978). It comprises 60 printed words that are presented to subjects to read aloud. Thus, rather than relying upon any sort of integrative or associative abilities, the NART-R and its various derivations rely only upon sight-word reading. Most of the words included in the NART- R are phonetically irregular, and thus, correct pronunciation generally depends upon prior familiarity with the words. The stimuli are presented in order of increasing difficulty, and range from words like "asterisk" to "ennui." As with any performance-based cognitive task, the NART-R does show some sensitivity to acquired brain dysfunction; nevertheless, it tends to remain relatively stable, even in the face of progressive dementia (Matt-Maddrey, Cullum, Weiner, & Filley, 1996). The NART-R does have limitations in terms of its applicability to individuals with very high and very low intellectual status, but correlates well with Verbal and Full-Scale IQ in many cases when there is little or no intellectual decline.

(iv) *Dementia Rating Scale (DRS)*. This is a popular instrument for the assessment of global cognitive functioning in patients with known or suspected dementia (Mattis, 1988). It has been widely used clinically as well as for research purposes, and has proven to be a reliable and valid screening tool that typically requires only 20–30 minutes (up to 45 minutes in some demented individuals). The total number of possible points on the DRS is 144, and Table 5 provides a general description of level of impairment on this measure. It should be noted, obviously, that any such listing provides only a global guideline for interpretation, as results on the DRS do vary according to age, education, and other background factors.

The DRS is made up of the following subtests: attention, initiation/perseveration, conceptualization, construction, and memory. Because of the screening nature of the test, higher functioning or minimally impaired individuals may achieve normal scores yet demonstrate evidence of impairment on more sensitive tests. For example, the memory component of the DRS assesses general orientation and includes some simplistic recognition memory tasks, while only two tasks focus on the assessment of delayed recall.

Although designed as a tool to screen for the presence or absence of dementia, patterns on the DRS have also been shown to be useful in helping to distinguish some types of dementias, although it should be noted that once cognitive impairment becomes severe, such differentiation on the basis of cognitive test results can be difficult or impossible. Despite is relative brevity, total scores from the DRS are quite useful in documenting cognitive decline over time and have shown to be predictive of nursing home placement (Smith et al., 1994).

(v) *Mini-Mental State Examination*. This is a very popular screening measure of global cognitive status. It is particularly useful in cases of dementia and may be used even in severely impaired individuals (Folstein et al., 1975). It is very brief (i.e., 5–10 minutes) and comprises 30 total points. Test items include an assessment of orientation to time and place, attention, language, constructional skill, and three word repetition and recall. It is recommended that standardized recall items (e.g., apple, table, penny or rose, ball, key) are used, as opposed to the original instructions of "name three objects" for patients to recall. Total MMSE scores correlate best with orientation and recall items, and significant variability can be seen among healthy subjects on three word recall (Cullum, Smernoff, & Thompson, 1993). Despite the limitations inherent in any brief measure of overall cognition, the MMSE has proven to be a valid and reliable screening tool, with utility in a number of populations and settings. Although the traditional cutoff for impairment is $<24/30$, the MMSE is sensitive to age and education effects, and appropriate norms should be used (Crum et al., 1993; Tombaugh, McDowell, Krisjansson, & Hubley, 1996).

Table 5 Dementia Rating Scale (DRS) and level of dementia.

115–130	Mild
100–114	Moderate
90–99	Moderate to severe
<90	Severe

4.11.4.2 Academic Achievement

These tests sample a range of abilities related to academic or scholastic levels of attainment. A number of omnibus achievement batteries exist and each has its relative strengths and limitations depending upon the purpose of assessment. Within the context of the adult neuropsychological evaluation, various components of different achievement tests are often administered. The more common measures sample a variety of abilities related to academic achievement (e.g., spelling, sight reading, reading comprehension, math) which can be compared with other neuropsychological skills and performances on related tests. Assistance in the diagnosis of learning disabilities can also be provided by these measures to the extent that specific deficiencies are identified.

(i) *Wide-Range Achievement Test-3rd Edition (WRAT-3)*. The WRAT-3, like its predecessors (WRAT, WRAT-R), provides for an assessment of written spelling, written mathematical, and sight-word reading skills (Wilkinson, 1993). It enjoys widespread use across the lifespan (age 5–75) and is relatively brief (i.e., approximately 20–30 minutes).

(ii) *Woodcock–Johnson Psychoeducational Battery-Revised (WJ-R)*. This is one of the most comprehensive batteries when used in its entirety for the individual assessment of global cognitive skill, general information, academic achievement, and interests (Woodcock & Mather, 1989). It has been used with children to adults, ranging in age from two to 90 years. The WJ-R Achievement Supplemental Battery provides a more focused assessment of academic achievement through the use of subtests that assess reading (both nonsense words and for meaning), math concepts, proof-reading, writing to dictation, and writing/sentence composition. Various cluster scores pertaining to different aspects of achievement and level of competence across domains can be examined in order to establish a profile of abilities.

(iii) *Peabody Individual Achievement Test-Revised (PIAT-R)*. The PIAT-R is used primarily for children, but offers norms from kindergarten through high school (up to age 19). It comprises the following subtests: general information, reading recognition, reading comprhension, mathematics, spelling, and written expression (Markwardt, 1989). Various subtests may be administered in order to screen for specific areas of difficulty, and because it is infrequently assessed by many other tests of cognition, the reading comprehension subtest is perhaps one of the most commonly used subtests of the PIAT-R as part of the adult neuropsychological evaluation.

4.11.4.3 Executive Functioning, Problem-solving, and Reasoning

This group of abilities is referred to by various names, and encompasses a variety of skills and functions. Judgment, reasoning, problem-solving, and abstraction are some of the more common skills within this domain that involve some of the most complex and integrative functions of the human brain. While such abilities are not specifically localized and rely upon the integration of various cortical and subcortical regions and pathways, the frontal lobes tend to play a relatively prominent role in many of these skills.

Formal neuropsychological evaluation represents the most efficient means of assessing these functions, although more informal administration of similarities, proverb interpretation, inhibition, and reasoning and judgment tasks also can be useful. Fluency tasks have also been shown to be useful in assessing executive or anterior cerebral functions—letter or phonemic fluency ("tell me as many words as you can think of that start with "R' within a minute") to assess left anterior hemispheric functions, and design fluency for anterior right hemispheric function (e.g., having patients draw as many unique nonreplicated designs as possible within a minute). Such tasks may be modified to further tax executive systems, for example, by alternating between different procedures ("name an animal, then a city"), although normative data on such procedures are lacking.

Judgment or reasoning tasks include questions such as "What would you do if you were stranded at the airport with only one dollar,?" or "Why should people visit the doctor when they are not ill?," or "The tiger was eaten by the Lion—who did the eating?" As with some other tests of higher cognitive function, proverb interpretation involves a variety of skills that cannot be readily distilled into a specific set of abilities. Administration of familiar (e.g., "A rolling stone gathers no moss") as well as unfamiliar proverbs (e.g., "The used key is always brightest") is recommended, however, since an individual's ability to interpret novel material may rely upon different skills compared to their ability to retrieve the common response to a more well-rehearsed task. Information about patients' planning abilities is also useful, whether assessed by a formal cognitive task or simply by inquiring about their plans for the future given their current situation. Malloy and Richardson (1998) outline a number of bedside and formalized procedures for the assessment of frontal/executive functioning. In evaluating results from various tests of executive abilities or frontal lobe function, it must be kept firmly in mind that such measures are not uniformly or invariably affected by damage to frontal systems (Bigler, 1988; Stuss & Benson, 1984), and that normal test results can be seen in some patients with clear evidence of frontal damage, just as impairment on the same tests can occur in patients with pathology outside the frontal lobes.

4.11.4.3.1 Tests of reasoning and problem-solving

(i) Wisconsin Card Sorting Test (WCST)

This is a popular measure of nonverbal reasoning and cognitive flexibility (Heaton, 1981; Heaton, Chelune, Talley, Kay, & Curtis, 1993). It requires subjects to sort a series of colored geometric designs into piles according to specific principles. Feedback is given as to whether each individual response is correct or incorrect, although subjects are not instructed as to what strategies they should be using. The WCST is sometimes touted as a measure of "frontal" functioning. Whereas the test has been shown to be relatively more sensitive to anterior brain damage in some studies (Heaton, 1981), it is important to keep in mind that the WCST is not exclusively a measure of frontal functioning, and can be sensitive to damage in other areas of the brain. Thus, impairment on the WCST in and of itself cannot necessarily be interpreted to suggest disruption of frontal brain systems. Nevertheless, patients who are disinhibited and have difficulty monitoring their responses will tend to be perseverative in their responses to this task. Furthermore, given the appropriate supporting pattern of anterior dysfunction based on behavior and results from other measures, results and observations from the WCST may assist in determining whether or not there is evidence of frontal brain system involvement. The most sensitive score from the WCST has proven to be the number of perseverative responses (Heaton, 1981), as many brain-injured individuals will tend to repeat the same strategy, despite corrective feedback. The ability to shift response strategies and perform such trial-and-error learning may also be a good predictor of various aspects of everyday functioning.

(ii) Category Test

The Category Test (Reitan & Wolfson, 1993) is one of the more sensitive measures of cerebral dysfunction, probably because of its complexity. This task requires subjects to generate and implement various problem-solving strategies across its 208 items. It comprises seven subtests, most of which require different principles to arrive at correct solutions. The subtests are generally arranged in increasing levels of difficulty, although two of the subtests actually require the same solution strategy, and the final subtest relies more upon memory, insofar as subjects must recall which response was correct when they saw that item in a previous subtest. The Category Test tends to be sensitive to dysfunction regardless of primary site of damage, although executive function impairment tends to have a particularly disruptive effect on results. Several versions of the Category Test are available (see Spreen & Strauss, 1998), including the standard machine version, a booklet version, a pamphlet version, and several computerized adaptations of the original test. Various short forms and child versions are also available.

(iii) Delis–Kaplan Executive Function Scale (DKEFS)

This is a battery of executive function tasks based on the Boston process approach that is being published by The Psychological Corporation (Delis, Kaplan, & Kramer, in press). Among other measures, it includes the California Sorting Test (CST), a measure designed to delineate more qualitative and multidimensional aspects of problem-solving, concept generation, and mental flexibility than other sorting tasks. The test consists of a series of cards that differ in shape and color and have different words printed on them. The cards can be sorted according to any of eight different principles. Initially, subjects are asked to sort the cards into two equal groups, without any further instruction. This procedure is repeated until no new groupings are performed. After each sort, subjects are asked to indicate what rule or principle they used. Subsequent trials include stating the sorting principle used by the examiner, and sorting in different ways according to cues. The test provides for an assessment of verbal and nonverbal concept formation and perseveration and allows for information to be derived regarding which component process may be principally affected. Preliminary studies of the CST have been promising in terms of the test's clinical utility (e.g., Beatty, 1993; Delis, Squire, Bihrle, & Massman, 1992; Greve, Farrwell, Besson, & Crouch, 1995). Also, because of the flexibility of the procedure, it is appropriate for a variety of ages, and normative data on individuals aged eight to 89 will be available.

4.11.4.4 Arousal and Orientation

Evaluation of these basic functions is a necessary prelude to the examination of higher level cognitive skills. These abilities represent some of the basic building blocks upon which higher abilities rely. For example, memory cannot usually be adequately assessed in a patient who is unable to attend to stimuli. Arousal refers to basic level of consciousness as a function of the reticular activating system. Arousal is often described as ranging from alert, drowsy, lethargic, stuporous, to comatose. Alternatively, hyperarousal can also be seen in terms of restlessness, agitation, and delirium. The delirious patient is confused and transiently disoriented. Patients may seem to come "in and out of it" from day to day or hour to hour, and mental status examination results may fluctuate accordingly. Assessing level of arousal is a clinical judgment, and often, if there are difficulties in this area, a behavioral description of what it takes to arouse a patient can be most important (particularly since a more detailed examination of cognitive abilities may not be possible).

Orientation is typically thought of in terms of the three general spheres of time, place, and person. Orientation to time is the most readily disrupted of these and can be assessed by asking patients questions about the current time, day, year, month, and date. Assessment of place is obvious (i.e. "Where are we now?"), although questioning about situational variables ("Why are you here?") is also useful along these lines. Orientation to person is the most resistant to disrupted cerebral functioning relative to time and place, and refers to a patient's ability to provide personal identifying information as well as being able to identify others who are familiar to him or her.

4.11.4.5 Attention/Concentration

The concept of attention is complex (e.g., see Mirsky, Anthony, Duncan, Ahearn, & Kellam, 1991). As some of the more basic cognitive abilities, attention and concentration are required for adequate performance on essentially all other cognitive tasks. Thus, it should be kept in mind that if a severe attentional impairment is present, associated difficulties should be manifest on tests of other cognitive abilities as well. General or undirected attention is related to overall arousal level and one's awareness of the environment. Additional divisions of attention into immediate vs. sustained attention also has clinical merit, as some patients can perform simple tasks of immediate attention, yet may have difficulty when asked to maintain their concentration longer. Measures of sustained attention, often referred to as "concentration" tasks, include measures designed to focus an individual's attentional skills for a more extended period of time, for example, over the course of a minute or longer. Informal assessment procedures may include having the examiner say a long series of random letters or numbers and having the patient indicate whenever they hear a designated target number or letter (e.g., the "A" test of attention; Strub & Black, 1988, p. 58).

Although it reflects a "global" brain activity, attention has some focal and lateralized correlates. Subcortical systems such as the reticular activating system in the core of the brainstem and midbrain, as well as diencephalic structures (e.g., thalamus) play a central role in the brain's ability to maintain arousal and focus attention. In terms of laterality issues in the visual domain, the left hemisphere attends to right hemispace and the right hemisphere attends to left hemispace. Hemi-attentional disorders, less severe than hemispatial neglect, may require double simultaneous stimulation to elicit, although evidence of hemi-inattention can also be detected in many cases by using line bisection tasks, number or symbol cancellation tasks, or even simple drawings to command or copy. As an extreme example, the patient with hemineglect may ignore one-half of their visual world, denying that their arm or leg belongs to them upon questioning, or eating only the food on one side of their plate. Hemi-inattention and neglect phenomena most often occur on the left side of hemispace, and the right hemisphere has been implicated as perhaps playing a predominant role in some aspects of attention. One simple test of neglect involves line bisection, wherein the examiner draws a series of horizontal lines of different length randomly on a page. The task for the patient is to bisect each of these with a small mark. Patients with neglect will show a tendency to skew their marks to one side (i.e., away from the neglected side) of each stimulus. A wide array of standardized clinical and experimental assessment techniques is available to measure aspects of attention and concentration, and only a few of these will be discussed.

4.11.4.5.1 Assessment of attention

(i) Digit Span (WAIS-III, WMS-III, WAIS-R, WMS-R)

The familiar Digit Span task requires subjects to repeat series of digits of increasing length. Digit span forward is a good measure of simple attention, and most healthy individuals perform within the seven plus/minus two span of apprehension range. While some consider the digit span test to be representative of a memory task, the demands on memory *per se* are minimal, and digit span forward is best considered as a measure of attention. To illustrate this principle, amnestic patients with Alzheimer's disease and Korsakoff's syndrome often demonstrate a normal digit span forward despite severe anterograde amnesia. Digit Span backwards represents a qualitatively different type of task that relies more upon working memory skills that should be considered separately from digits forward (Reynolds, 1997).

(ii) Digit Symbol (WAIS-III, WAIS-R)

This is a complex measure of attention, working memory, visual scanning, and psychomotor speed. Subjects are required to learn to associate numbers with symbols and must fill in the symbol that is paired with each of nine numbers under time constraints (90 seconds). As noted, it tends to be the most sensitive of the WAIS-R subtests to brain dysfunction, and is often used separately from the Wechsler scales.

(iii) Symbol Digit Modalities Test

This is very similar to the Wechsler Digit Symbol test, in that it requires the written substitution of numbers and symbols. In this test, however, subjects must fill in the specified number that goes with the indicated symbol (Smith, 1982). An oral version is also available wherein the patient responds verbally with the number associated with each symbol they come to. Ninety seconds are allowed in this test as well, and it has been used in a large number of neurobehavioral studies since its inception. In some research settings to assess medication effects, subjects complete the test repeatedly prior to the beginning of the study in order to decrease subsequent practice effects.

(iv) Digit Vigilance Test

This represents a popular and well-normed (Heaton, Grant, & Matthews, 1991) version of the traditional number cancellation task. In this test, subjects must cross out all of a specified number they come to on pages that are filled with rows and columns of single digits (Lewis & Kupke, 1977; Lewis & Rennick, 1979). The task requires visual scanning, psychomotor speed, and sustained concentration, insofar as it typically takes several minutes to complete the two-page version of this task. Additional information regarding lateralized inattention can also be derived from this and similar tasks.

(v) Visual Search and Attention Test (VSAT)

This provides similar information to Digit Vigilance regarding sustained visual concentration, but includes verbal and nonverbal stimuli (Trenerry, Crosson, DeBose, & Leber, 1990). The VSAT consists of four tasks (two for practice) that require subjects to cross out target items from 10 rows of 40 stimuli (letters or numbers) on each version. Scoring for left- vs. right-sided errors in addition to an overall attention index is included.

(vi) Bells test

This is a symbol cancellation task similar to Digit Vigilance, although the target in this case is a small picture of a bell that is repeated within a quasirandom array of 315 small visual figures on a page (Gauthier, Dehaut, & Joanette, 1989). One of the advantages of this task can be that patients who utilize more systematized visual search strategies (e.g., scanning left to right and from row to row) on more symmetrically organized tasks such as Digit Vigilance may show impairment more readily on the more randomly arranged bells.

(vii) Continuous Performance Test (CPT)

Several versions of this computerized test of sustained concentration have been developed, and variations on the basic task have been used in research and clinical settings since the 1950s. In one common format, the CPT presents several series of single visual stimuli (usually letters) projected at brief intervals. Subjects must respond when a letter was preceded by a designated target letter. In Connor's CPT (Connors, 1995), subjects are asked to press the appropriate key for any letter presented, except for the letter S. Multiple trials of different interstimulus intervals are presented, and scoring includes reaction times, number correct, and errors of omission and comission.

4.11.4.6 Language

Language is a central part of the human experience, and a careful evaluation of the core components of language function are an important part of the neurobehavioral examination. Because of its complexity and multifaceted nature, an assessment of "language" requires multiple tasks. Note that some components of language (e.g., basic comprehension and expression) are amenable to observation during even casual interactions with patients, as well as during most of the traditional mental status examination. Recall that the left hemisphere is dominant for language functions in most people (particularly in right-handers, wherein over 95% are left-hemisphere dominant for language), although a minority of individuals (particularly left-handers) have bilateral speech representation or may even have their primary language center in the right hemisphere.

In screening for language disturbance, several primary areas should be assessed: verbal expression, naming, repetition, comprehension (oral and written), reading, and writing. Depending upon the function disrupted, performances on tasks involving these skills may provide useful information in terms of localization of dysfunction. Anterior dominant hemisphere systems are involved in expressive language (e.g., Broca's area), while more posterior regions are involved in receptive language (e.g., Wernicke's area). Aphasic disorders can occur as a result of a disruption of either of these areas, interconnecting cortical and subcortical pathways, or in cortical association areas nearby. The major aphasic syndromes are listed in Table 6.

Several comprehensive batteries for assessing aphasia have been developed, including the Boston Diagnostic Aphasia Examination (BDAE; Goodglass & Kaplan, 1987), the Multilingual Aphasia Examination (MAE; Benton & Hamsher, 1989; Benton, Hamsher, Rey, & Sivan, 1994), and the Western Aphasia Battery (Kertesz, 1982). Routine neuropsychological evaluations vary widely in terms of the depth with which language is examined. At a basic level, to begin to assess language function, the following areas and procedures should be considered.

Table 6 Common aphasic syndromes and abilities affected.

Aphasia Type	*Fluency*	*Naming*	*Repetition*	*Comp.*	*Rdg. comp.*
Broca's	Poor	Poor	Poor	Good	Good
Wernicke's	Good	Poor	Poor	Poor	Poor
Conduction	Good	Poor	Poor	Good	Good
Global	Poor	Poor	Poor	Poor	Poor
Transcortical motor	Poor	Poor	Good	Good	Good
Transcortical sensory	Fluent	Poor	Good	Poor	Poor
Mixed transcortical	Poor	Poor	Good	Poor	Poor
Anomic	Good	Poor	Good	Good	Poor

(i) Expressive language/fluency. Spontaneous speech can be examined during clinical interview and history-taking. This includes an assessment of rate of speech, prosody, grammatical complexity, and use of vocabulary.

(ii) Confrontation naming refers to the ability to name objects or representations of objects. This can be assessed in a rudimentary way by having the patient name things in the room or things you are wearing or holding. A much more sensitive means of assessing naming ability is to show the patient pictures of objects and request that they say what it is. Clinical experience suggests that the further the representation is from real life (e.g., a line drawing vs. a photo or real object), the more sensitive the task will be to dysnomia. An important note is that some degree of dysnomia is seen in most types of aphasia.

(iii) Repetition is examined by having the patient repeat single words (e.g., "paper," "ball," "comb") and phrases of increasing length and complexity (e.g., "The boys played baseball," "The vat leaks," "He is the one who did it"). Careful notation of the specific errors made (e.g., omissions, paraphasias) should be made, as these may merit further exploration using more standardized tasks.

(iv) Comprehension is also assessed in interview and during the performance of tasks upon request by the examiner (i.e., does the patient seem to understand what is being asked, or do tasks require additional explanation?). Examples of comprehension tasks include: "Point to the ceiling, then to the floor" "Do two pounds of flour weigh more than one?" "Place the quarter to the right of the penny and pick up the dime."

(v) Reading is examined readily by having the patient read single words, something they have written, and/or read sentences written by the examiner. Reading comprehension can also be tested by having the patient read a passage from a newspaper or magazine and then asking them questions about what they read (a number of standard brief tasks are available).

(vi) Writing is tested by having the patient write their name (a highly over learned task), specific words or a sentence to dictation, or perhaps a sentence or paragraph on a topic of interest (which also allows for an assessment of sentence structure, punctuation, and grammar use, etc).

The assessment of general expressive and receptive language skills encompasses a large array of tests and procedures, and is well beyond the scope of this section. Nevertheless, various language skills should be sampled in the comprehensive neuropsychological evaluation, at least at a cursory level. This may entail the administration of specific tests (e.g., the Token Test to evaluate comprehension), or may reflect more of a basic examination of an individual's ability to repeat, speak, write, and comprehend. Various types of linguistic errors can be seen during speech and these various tasks and should be noted when they occur. Paraphasias can be semantic or verbal (i.e., the substitution of an incorrect word), phonemic or literal (i.e., the incorrect substitution of phonemes within a word or a similar sounding word), or neologistic (i.e., made-up, nonsense words).

4.11.4.6.1 Global language assessment

(i) The Aphasia Screening Test

This test is a popular and extremely brief measure that employs single- or several-item sampling of a variety of language skills (e.g., reading, writing, naming, comprehension) (Reitan & Wolfson, 1986). For tests such as this, it must be kept in mind that a single error on a particular item, while potentially significant, may not reflect an underlying deficit. Instead, this may reflect the brief nature of the task and its sensitivity to response variability during a neuropsychological examination. Hence, individual errors on such tasks should be followed up with additional tests, lest an overinterpretation of results occur.

(ii) The Wechsler Vocabulary Subtest

This is a subtest of the Wechsler scales (WAIS-III, WAIS-R) and provides a good assessment of vocabulary and basic word knowledge. As previously noted, the Vocabulary subtest tends to be relatively insensitive to acquired cerebral damage in most cases, and may provide an index from the Wechsler scales regarding an individual's likely level of premorbid functioning. Unlike the NART, however, the Vocabulary subtest, with its reliance upon subject-generated word definitions, tends to be somewhat more susceptible to the effects of brain injury, and may also be impacted by conditions that affect initiation of responding. The WAIS-R-NI version includes provisions for multiple-choice responding for those patients who may have difficulty with verbal expression. The correlation between WAIS-R Vocabulary and FSIQ is 0.81 (0.85 with VIQ), and the WAIS-III Vocabulary correlation with FSIQ is 0.80 (0.83 with VIQ), also makes the Vocabulary subtest appealing when a brief estimate of current verbal intellectual functioning is desired.

(iii) Boston Naming Test (BNT)

This is a popular quantitative measure of confrontation naming ability (Kaplan, Goodglass, & Weintraub, 1983). Because of the prominence of dysnomia in the various aphasic syndromes, the assessment of word-finding has become a component of many neuropsychological test batteries. The standard BNT consists of 60 line drawings of objects of decreasing familiarity (e.g., ranging from "comb" to "abacus"). Several short forms of the BNT are also available (Franzen, Haut, Ranking, & Keefover, 1995; Lansing, Ivnik, Cullum, & Randolph, in press) for use when a more brief assessment of naming is desired. As noted, clinical experience indicates that the ability to name drawings of items is a much more sensitive means of assessing dysnomia than having patients name articles that are physically present in the room.

(iv) Verbal fluency (letter and category)

Clinical tests of verbal fluency come in two primary varieties: letter or phonemic fluency and category or semantic fluency (Benton & Hamsher, 1967; Borkowski, Benton, & Spreen, 1967). For letter fluency, subjects are asked to generate as many words as possible in 60 seconds that begin with a specified letter. Norms and alternate forms are available (Kozora & Cullum, 1994; Spreen & Strauss, 1998), although the most common sets of letters in use today include F, A, S, and C, F, L, with P, R, W serving as an alternate form. Category fluency is most commonly assessed by having subjects generate as many animals as they can think of in 60 seconds, with other variations of this task including fruits, vegetables, first names of people, supermarket items, cities, and US states.

Performance on letter (phonemic) and category (semantic) fluency tasks has been analyzed in number of populations, and it has been shown that the abilities involved in each task are dissociable. For example, in patients with Alzheimer's disease, it has been commonly reported that patients show a greater difficulty on category fluency, and often do somewhat better on letter fluency. This is thought to be related to the breakdown in semantic knowledge as seen in patients with Alzheimer's disease, unlike patients with subcortical dementias (e.g., see Chan et al., 1995). Along these lines, Moscovitch (1994) provides evidence to suggest that letter fluency is more of a frontally-mediated task, while category fluency relies more upon temporal lobe structures.

4.11.4.7 Visuospatial Skills

This cognitive domain refers to the ability to process visual or nonverbal information. In the most common visuospatial task, patients are asked to draw a specific shape (e.g., intersecting pentagons). More difficult tasks include drawings of three-dimensional figures (cube, house). Drawings to command can be compared with patients' copies of drawings to see if the presence of a model facilitates performance. Three-dimensional constructional tasks also exist, such as replicating designs using blocks. These and related tasks require various levels of visuoperceptual and visual-integrative skills, in addition to a motor output (e.g., graphomotor or manipulospatial).

Various standard tasks and stimuli are available for clinical use. Prominent visuospatial errors can be readily detected on such tasks, most often in association with right hemisphere damage (primarily parietal dysfunction). Lateralized errors in drawings, embellishment or paucity of creations, perseveration, rotations, intrusions, and loss of *gestalt* or detail can all be observed and may provide useful diagnostic and descriptive information. For example, patients with right hemisphere damage will tend to have more difficulty maintaining the overall *gestalt* of designs, whereas left hemisphere dysfunction more often results in problems recreating details of figures. Because many of these tasks require visual perception and a motor response, the clinician must use caution in interpreting visuoconstructional impairments when primary visual, perceptual, or motor disturbances are present.

4.11.4.7.1 Visuospatial tasks

A variety of drawings are commonly used in neuropsychological settings to assess graphomotor visuoconstructional ability. Some drawings have gained widespread popularity such as clocks, drawings of crosses, and three-dimensional cubes. A dissociation can be seen in some patients between their ability to spontaneously draw a specified design or item to command and their ability to reproduce it from a model presented to them. Obviously, the production of any drawing involves a variety of skills, and an interpretation of impaired visuoconstructional ability should only be done once a thorough assessment of the various component processes has been undertaken. For example, patients with basic motor or movement disorders will often produce impaired drawings, which should not be interpreted as a visuoconstructional deficit if their level of motor impairment can just as easily explain their poor productions.

The term "constructional dyspraxia" is often used to describe impaired visuoconstructional abilities. Unfortunately, the term is often misused and overused in clinical practice. Technically, the term refers to an impairment in the ability to construct visuospatial figures or drawings, whether two- or three-dimensional. Thus, a patient who demonstrates an impaired copy of a key from the aphasia screening test should not be considered to have constructional dyspraxia if they show normal performances on other visuoconstructional tasks such as WAIS-R Block Design, for example. Furthermore, it is important to obtain more than one drawing sample from a patient, as the degree of complexity of one stimulus may fail to elicit an impairment, whereas another one of greater complexity or less familiarity may reveal evidence of difficulty in this domain. The clinician's familiarity with developmental and general norms on a given drawing procedure are critical. This is particularly important on drawing tasks that do not lend themselves to highly detailed scoring procedures. Even when such scoring procedures are available, clinical interpretation based on a careful review of the component processes and the actual drawings produced can be critical. For example, the Rey–Osterrieth complex figure has seen the development of a variety of scoring systems over the years (see Lezak, 1995; Spreen & Strauss, 1998). Although more recent attempts such as the Boston qualitative scoring system (Stern et al., 1994) have attempted to capture more of the essential details and qualitative aspects of the design, quantitative scoring alone may prove inadequate in the absence of careful inspection by a seasoned clinician.

(i) Clock drawing test

This is a staple for many clinicians across disciplines involved in mental status examinations and neurobehavioral assessment, and actually can provide a wealth of information regarding a variety of cognitive skills. First, the reproduction of the face of a clock from memory requires some familiarity with such a stimulus. In some cultures, this represents a highly overlearned icon, and thus, should be reproduced even by children without significant difficulty, providing they are able to tell time.

Typical instructions (Goodglass & Kaplan, 1987) for the clock drawing test are to "Draw the face of a clock showing the numbers and the hands set to ten after eleven." The additional instruction to include all of the numbers on the clock can be helpful in some cases, particularly since some clocks and watches do not include a complete set of alphanumeric symbols. The instruction to set the hands at a specified time is also critical, and even when gross visuoconstructional abilities and the overall *gestalt* of the clock may be correct, time-setting errors may reflect problems with executive functions and/or memory. It is also important that the instructions include setting the hands to a time that is not too readily obvious or overlearned, so as to reduce the likelihood of an individual getting the time correct by chance. Various scoring procedures for clock drawings have been established (e.g., see Freedman, Leach, & Kaplan, 1994; Kozora & Cullum, 1994; Royall, Cordes, & Polk, 1998), although careful visual inspection and qualitative analysis, in addition to the application of a particular preferred scoring system, is important from a clinical interpretive perspective.

Along these lines, some of the more common errors that can be seen on the clock drawing test include confusion, gross distortion, and constructional dyspraxia (Figure 9(a)), aspects of unilateral neglect (Figure 9(b)), stimulus-boundedness and perseveration (Figure 9(c)), and errors in hand-setting (Figure 9(d)). Figure 9(d) was drawn by a patient with mild Alzheimer's disease and demonstrates a common conceptual stimulus-bound response by their setting of the hands at the 10 and 11 in order to depict "ten after eleven." Comparison of clock drawings done to command and under copy conditions have also demonstrated utility in some differential diagnostic situations (e.g., Libon, Malamut, Swenson, Sands, & Cloud, 1996).

(ii) Aphasia Screening Test

Although designed primarily as a brief screening measure of gross language disturbance, the aphasia screening test contains several drawings,

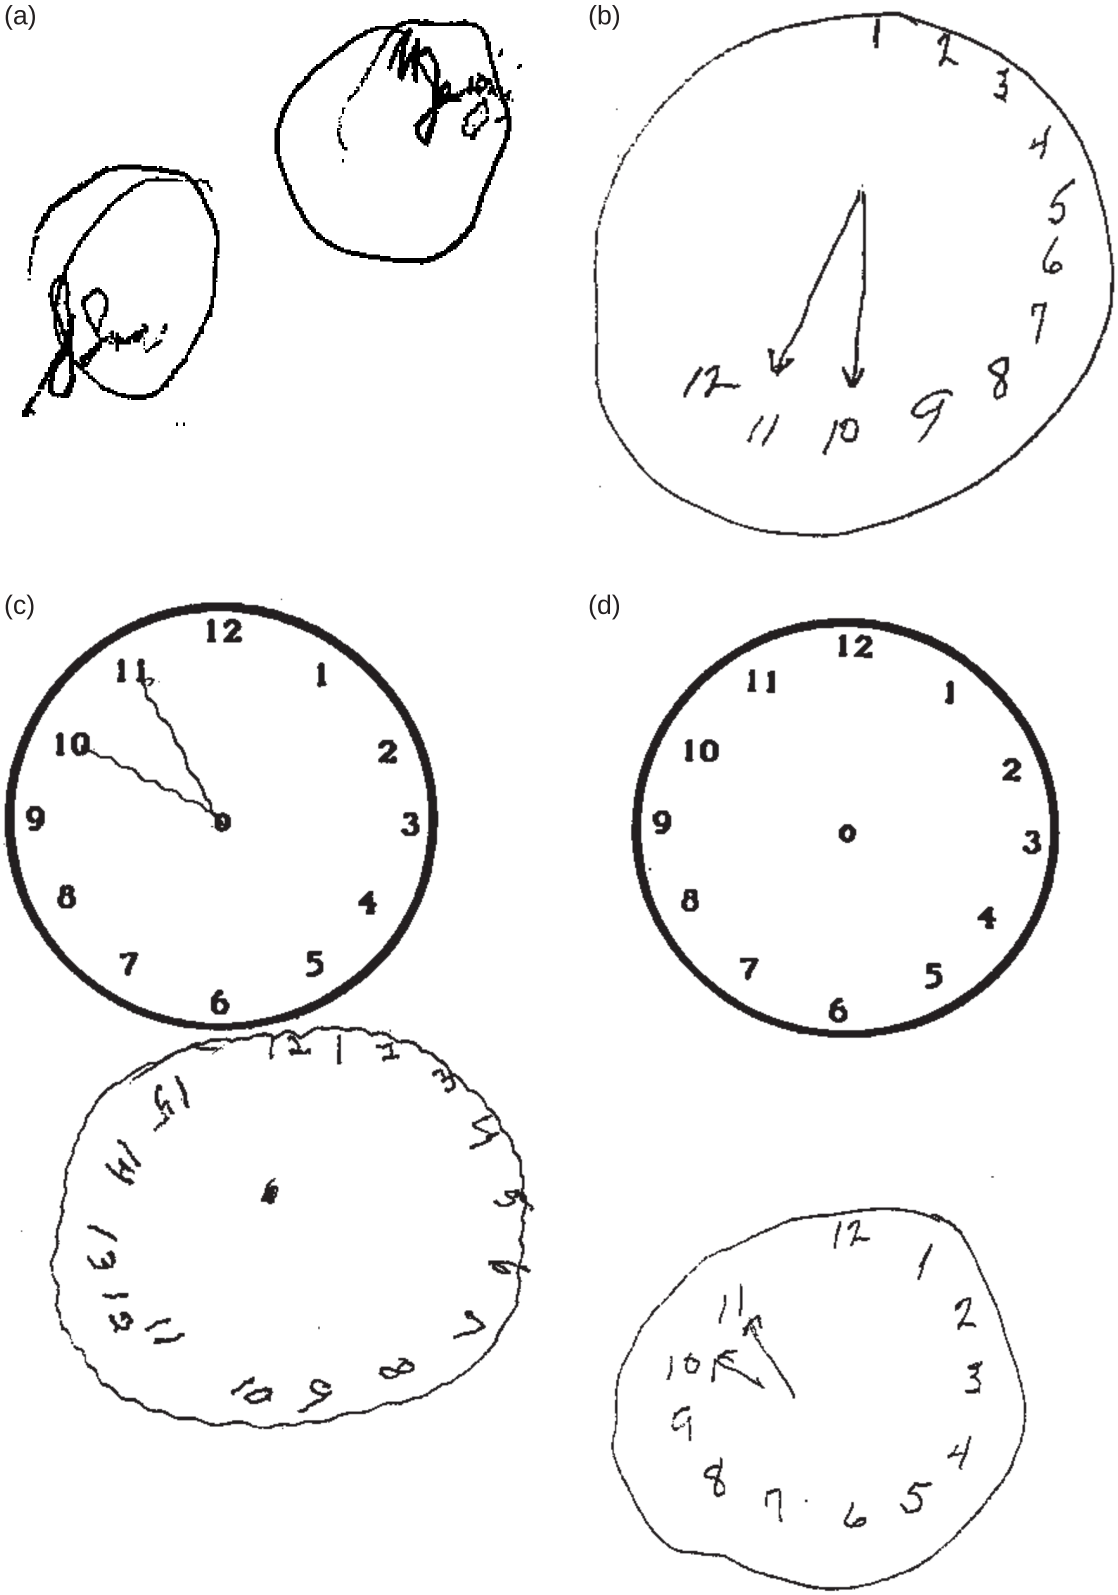

Figure 9 Clock drawings from patients showing various error types to command (9a, 9b) and copy (9c, 9d).

including a square, triangle, Greek cross, and a skeleton key (Reitan, 1984). Traditional qualitative scoring procedures for these drawings exist, although as with other similar tasks, visual inspection by a trained clinician is extremely important, and one needs to be familiar with the wide range of variability seen in the normal population as well. The copy of the Greek cross or similar crosses is a very common graphomotor constructional task, and despite its relative simplicity, nevertheless does require a variety of skills, including visuoperception, planning, graphomotor control, and sequencing.

(iii) Block Design

The Block Design subtest from the WAIS-III or WAIS-R provides one of the most common means of assessing visuoconstructional ability. This familiar task requires the replication of red and white designs using three-dimensional colored blocks. As with other visuoconstructional tasks, careful observation of the patient's performance during the procedure can yield very important information, as can the qualitative nature of the designs that are produced. This serves as some of the rationale for including spaces for noting the designs produced by patients in the WAIS-III summary form, as the same score can be achieved for a variety of reasons. To illustrate, Figure 10 depicts the designs from two brain injured patients.

Technically speaking, both productions would receive a WAIS-III score of zero, yet they obviously reflect very different underlying aspects of dysfunction. As has been discussed by Kaplan and co-workers (Kaplan, 1990; Milberg, Hebben, & Kaplan, 1996), many patients with right hemisphere dysfunction tend to break the overall square configuration of the design, as they have difficulties in processing the *gestalt* of figures. In contrast, patients with damage to the left hemisphere tend to more frequently make internal rotation errors. In Figure 10 , the design on the left was, in fact, produced by a patient with a large subcortical infarct in the left-hemisphere, and the design on the right was produced by a patient with a large middle cerebral artery stroke.

(iv) Rey–Osterrieth complex figure

Although the Rey–Osterrieth figure is perhaps most well known as a measure of nonverbal memory, the copy of the figure provides an excellent sampling of visuoconstructional skills (Corwin & Bylsma, 1993; Osterrieth, 1944; Rey, 1941). In addition to providing data pertaining to an individual's organizational approach to the task (assuming the sequential replication of

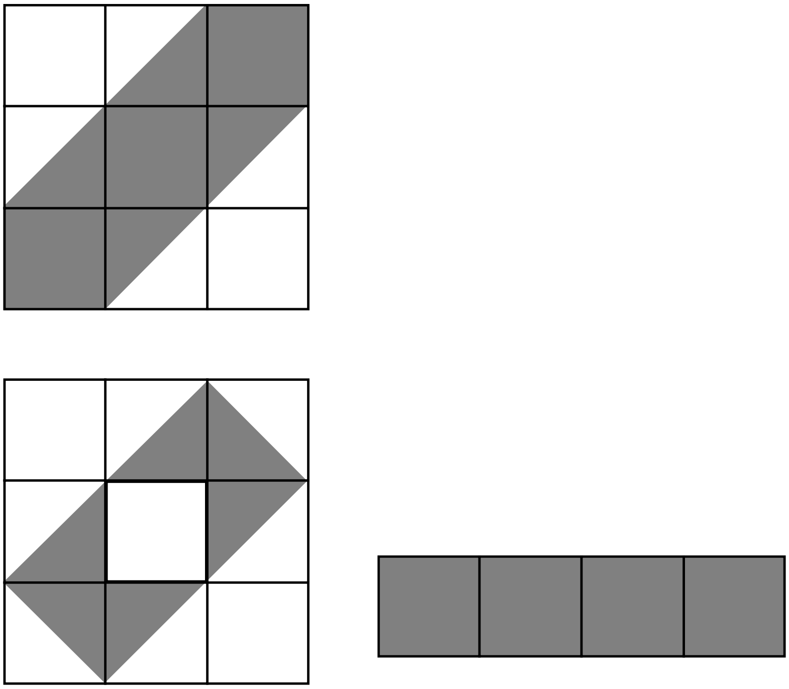

Figure 10 Block Design reproductions (top = model) of a patient with left hemisphere damage (left) and right hemisphere damage (right) showing characteristic internal detail and configural errors, respectively, Note that technically, both reproductions would receive a score of zero, although they reflect very different types of errors.

the figure is somehow carefully tracked and recorded), visuoperceptual as well as visuospatial and graphomotor constructional skills are necessary components to this task. Information pertaining to lateralized dysfunction can also be obtained in some cases (Rapport, Dutra, Webster, Charter, & Morrill, 1995). This requires not only careful attention to the *gestalt* vs. internal details of the figure, but also to left–right and quadrant by quadrant analysis, in addition to an assessment of item and figural rotations and perseverations. Gross omission or distortion of part of the figure might also implicate lateralized dysfunction. For example, Figure 11(a) depicts the Rey–Osterrieth from a patient following the rupture of a right middle cerebral artery aneurysm. The Rey–Osterrieth stimulus figure is presented in Figure 11(b).

4.11.4.8 Memory

Memory is one of the most common clinical complaints of patients referred for neuropsychological evaluation. This represents a complex set of abilities that are all too often subsumed under a generic and unitary rubric of "memory." While multiple memory systems and skills have been identified and discussed over the years (Schacter & Tulving, 1994), some of the more useful concepts from a clinical standpoint include immediate, recent, and remote memory. Because of the multifactorial nature of memory and the use of various labels and terms to describe this set of abilities, some basic definitions of memory concepts are in order before proceeding to a discussion of common clinical memory assessment tools.

Immediate or working memory refers to a very brief memory store where information is retained for a matter of seconds before it decays, in the absence of rehearsal. A prime example is going to the phone book to look up a new number, walking across the room to the phone, and dialing the number. Unless the number is of particular relevance or is rehearsed, it will probably be forgotten immediately or shortly after the call. Evidence suggests a particularly prominent role of the prefrontal cortex in working memory.

Recent memory is the ability to encode new information and remember things learned in the recent past. Temporal lobe structures (particularly the hippocampal formation) are particularly important in this stage of information acquisition. Examples include remembering a few words or an address presented several minutes ago, or remembering what you had for breakfast. This type of memory is what is routinely assessed clinically and is what allows us to learn new information each day.

Remote memory pertains to the ability to recall information from the distant past, for example, from many years ago. Remote memory involves the recollection of previously stored data (over the course of months or years) that has been rehearsed or retrieved multiple times and in various contexts (e.g., where you went to high school, aspects of your job, stories you have learned, etc.).

In most cases of acquired cerebral dysfunction, recent memory is the most vulnerable to damage (i.e., anterograde amnesia), while remote memory tends to remain relatively more intact. However, retrograde amnesia does occur, and often extends back into time (sometimes decades, as in Korsakoff's syndrome) in a temporal gradient fashion, with a greater disruption of more recent memories. The clinical assessment of memory involves multiple steps and procedures. At a basic level, obtaining a history from a patient involves their remote memory abilities. Questions pertaining to familiar information historical events can also be useful (e.g., as in the WAIS-III Information subtest).

Recent memory is best informally assessed by presenting the patient with a few words, name and address, or a paragraph to recall. Here it is essential to stress that delayed recall of such information must be examined. For example, amnestic patients can often repeat back even a brief story immediately after it is presented, and it is only after additional time has elapsed (e.g., 10–15 minutes) that their full amnestic deficit may be manifest. The use of multiple memory procedures is also recommended, since significant variability even among healthy normal subjects can be seen on singular brief tests of memory. Furthermore, the use of standard or favorite memory stimuli is also encouraged (i.e., rather than inventing new stimuli for every patient), since the specific content of items can have a profound effect on their ability to be recalled (e.g. "rose, ball, key" or "apple, table, penny" are easier for most people to remember than "brown, honesty, tulip," and these sets are no doubt easier to recall than "abstemious, benign, pusillanimous"). Regardless of what brief memory tasks are employed at the bedside, it must be kept in mind that more lengthy psychometric procedures may be required to elicit deficits in many cases.

4.11.4.8.1 Clinical assessment of learning and memory

Memory can fail for a wide variety of reasons. Problems with attention/concentration which result in an inefficiency in the ability to attend to and learn new information may be perceived as

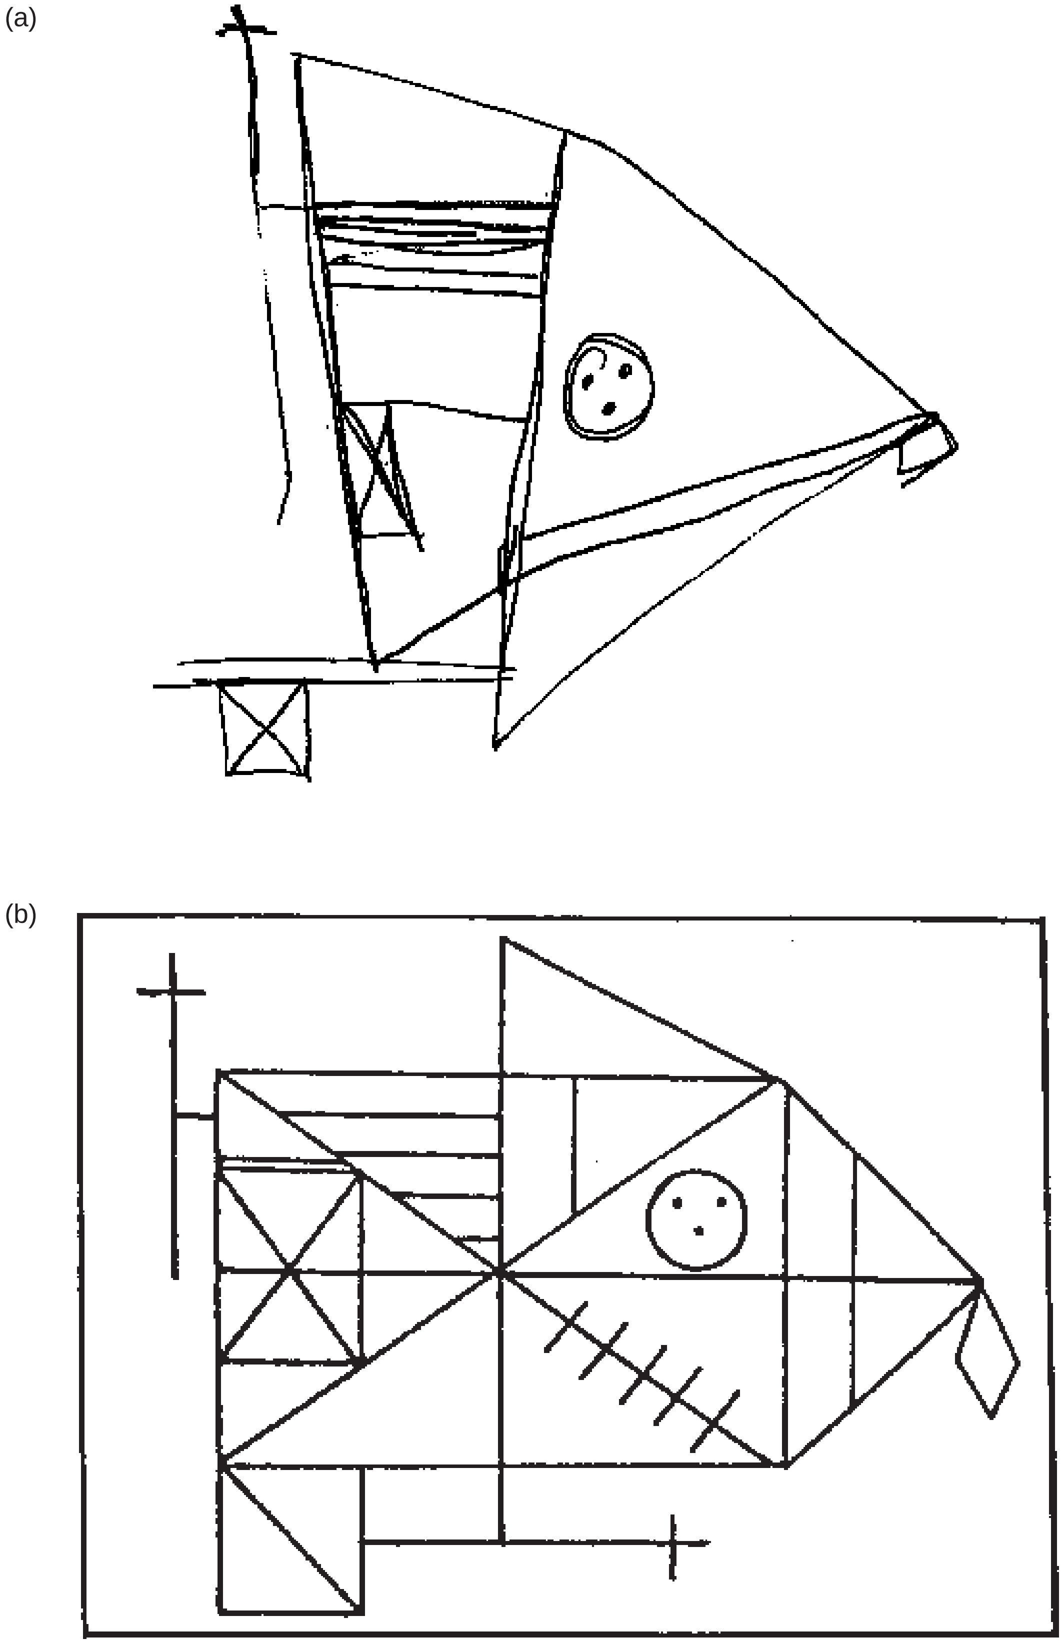

Figure 11 Rey–Osterrieth copy by a patient with right hemisphere damage (11a). Note the distortion of the left side of the figure in particular. The original Rey–Osterrieth figure is (11b).

a problem with memory, for example. If information is not efficiently encoded, it obviously cannot be stored for later recall. Subjectively, this can be perceived as a problem with remembering. Other component abilities that can interfere with efficient memory functioning include language disturbance and problems in visuospatial processing, depending upon the nature of the material that is to be remembered.

Some of the different learning and memory types that have been proposed include episodic, semantic, procedural, implicit, explicit, and working memory. A discussion of these is beyond the purpose of this chapter, although detailed elaborations can be found in sources such as Schacter and Tulving (1994) and Squire (1987). At a basic level, most of the clinical assessment approaches to memory involve an examination of episodic memory, insofar as patients are required to recall material that was presented to them earlier. Typically this material is presented in an explicit memory paradigm wherein patients are instructed to learn and remember information, although in some procedures, implicit recall is required. One example of the latter would be the typical administration of the Rey–Osterrieth complex figure, wherein subjects are asked to copy the complex design, and once that is done, they are asked to recall it from memory, without ever having been instructed to "remember" the figure.

(i) Verbal and nonverbal memory

Verbal learning and memory tasks (e.g., word lists, verbal paired associates, and story recall) have been shown to be strongly associated with left temporal lobe functioning (Chelune, 1995; Hermann, Wyler, Richey, & Rea, 1987). More debate exists about so-called "nonverbal" measures of memory and their respective sensitivity to right temporal lobe dysfunction (Barr et al., 1997). Some of this discussion centers around the nature of nonverbal stimuli that are employed in many popular memory tests. For example, many of the figures that are used are verbally encodable or lend themselves quite readily to verbal labels, thereby perhaps involving left temporal lobe structures to a significant degree. Other debate exists with regard to the specificity of functioning of the right temporal lobe, as some argue whether there is a "nonverbal" memory system at all. This is perhaps nowhere better illustrated than in cases of right temporal lobectomy in the treatment of intractable epilepsy, wherein scores on some nonverbal memory tests may show no significant change following surgery (Naugle, Chelune, Cheek, Luders, & Awad, 1993).

(ii) Forgetting rates

An important concept in memory assessment includes the examination of delayed recall for newly learned information. The simple assessment of the ability to immediately recall newly presented information, for example, may not be significantly impaired in individuals with even gross memory disorders. This can be illustrated by many patients with Alzheimer's disease, as their ability to recall a brief paragraph that was just presented may be relatively intact, even though they show a rapid rate of forgetting over time. The seminal work by Butters and colleagues (e.g., Butters, 1985) clearly demonstrated the importance of including delayed recall techniques in the assessment of memory disorders. Along these lines, the calculation of forgetting rates or percent loss over time has proven most useful in clinical memory assessment.

(iii) Patterns of memory dysfunction

In addition to examining immediate vs. delayed recall and looking at forgetting rates, it is important to carefully analyze patterns of memory performance across individual patients. Different disorders are now known to demonstrate characteristic memory profiles in many cases, and the degree to which an individual's profile matches what is known in the literature may be of great assistance in differential diagnostic situations. As one example, patients with Alzheimer's disease typically show impoverished learning, rapid forgetting, faulty encoding and storage of information, and a tendency to rely upon more passive, less efficient learning strategies (Bondi, Salmon, & Butters, 1994). Their recall of stimuli that has been recently presented to them is often marked with intrusion errors (i.e., inserting features of related or unrelated stimuli during their recall of recently presented material). Like the amnestic Korsakoff's disease patient, individuals with Alzheimer's disease may tend to confabulate during recall in an apparent attempt to "fill in" for the material which they are no longer able to effectively organize or recall.

Another example of a memory pattern that has been shown useful in clinical assessment is the distinction between recall and recognition. Free recall involves the recollection of previously presented material. Cued recall additionally involves the presentation of a cue to help "jog" an individual's memory. For example, if a recently presented story was about a woman who was robbed, a recall cue might be, "it was about a woman." The next step in assisted memory is the recognition paradigm, wherein subjects are presented with several possible stimulus items that were presented to them earlier, and the task is simply to identify which item was previously presented. It has been argued that such recognition paradigms represent "easier" tasks, insofar as the load on memory processing is diminished. An everyday analogy would be driving to a new location, being unable to remember the name of the street, but then quickly recognizing the name of the street once it is seen. Some patients with various forms of amnesia demonstrate the ability to learn, even in the absence of awareness (e.g., Schacter & Tulving, 1994), and such mechanisms may be involved in recognition memory performance.

4.11.4.8.2 Clinical memory tests

An enormous array of published measures exist for the clinical examination of memory skills, and an even larger number of tasks have been developed in the experimental and cognitive psychology literatures. A few of the tests that are commonly used in clinical practice are discussed below, and an attempt has been made to avoid too many overlapping measures. Before presenting a brief overview of individual memory assessment tools in common clinical use, one popular omnibus memory battery will be discussed. It should be noted, however, that many of the subtests which comprise the more global memory batteries are often used individually; hence, brief mention of some of the more popular subtests will be made in the following subsections.

4.11.4.8.3 Memory batteries

(i) Wechsler memory scales

This series of memory assessment batteries has a long tradition and represents some of the most popular clinical memory tests in use in the late 1990s. Because each version of the test contains various significant revisions, they will be discussed separately, although there is some overlap of core concepts and general approaches to memory testing.

(a) Wechsler Memory Scale (WMS). This was the original version (Wechsler, 1945) of the popular Wechsler Memory Scales. The WMS was designed to provide a brief assessment of overall memory function by combining several tests of attention and memory. The subtests include the following: Personal and Current Information, Mental Control (e.g., counting down from 20, reciting the alphabet, counting by threes), Digit Span, Logical Memory (paragraph recall), Visual Reproduction (immediate recall of a series of geometric figures), and Associate Learning (learning verbal associations such as "metal–iron," "crush–dark." A total Memory Quotient (MQ) score could be derived to permit a more direct comparison with traditional IQ scores. Thus, a significant discrepancy between MQ and IQ scores would indicate a particular impairment of recent memory. In its original version, the WMS assessed only immediate recall of verbal and nonverbal material, in addition to orientation/mental control and verbal paired associate learning. Importantly from a memory assessment standpoint, Russell (1975) added delayed recall procedures to the Logical Memory and Visual Reproduction subtests, resulting in what became know as the Russell revision of the WMS.

(b) Wechsler Memory Scale-Revised (WMS-R). Administration and scoring procedures were revised and made more specific in this version of the WMS, and the floor effects of the previous test were addressed (Wechsler, 1987). Importantly, delayed recall measures were built into several of the subtests so as to assess forgetting over time. A number of new subtests to assess various aspects of memory were added, which allows for a more comprehensive assessment of different aspects of learning and memory, but also adds substantially to the time. Individual subtests include Information and Orientation, Mental Control, Digit Span, Visual Memory Span, Logical Memory I (immediate recall) and II (delayed recall), Verbal Paired Associates I and II, Figural Memory, Visual Paired Associates I and II, and Visual Reproduction I and II. The following memory index scores can be derived: Attention/Concentration, Verbal Memory, Visual Memory, General Memory, and Delayed Memory. The WMS-R was a welcome revision to the WMS, addressing some of the concerns about the earlier scale and providing much-needed improvements in standardization and norming procedures. While it has proven to be useful in differentiating various memory-disordered populations (Tröster, Jacobs, Butters, Cullum, & Salmon, 1989), the utility of the Verbal and Nonverbal Memory indices in distinguishing lateralized cerebral dysfunction is questionable (Loring, Lee, Martin, & Meador, 1989). In addition to the norms available in the test manual (age 16–74), normative data for the elderly (up to age 94) are available (Ivnik et al., 1992).

(c) Wechsler Memory Scale-III (WMS-III). This represents the most recent revision of the WMS (Wechsler, 1997). The WMS-III was normed along with the WAIS-III, thereby providing for IQ and memory scores derived from the same standardization population. This allows for more direct comparisons between IQ and memory scores which should facilitate

inferences regarding the likelihood of acquired memory impairment. The standardization sample was selected to be more representative of the US population, and included individuals up to age 89. New subtests were added, and some are optional in terms of the derivation of memory index scores. Scoring procedures were further refined, updated, and expanded, and the available computer-generated scoring greatly facilitates the comparison of WMS-III and WAIS-III scores alike. Separate scores comparing working memory and immediate memory, auditory (previously referred to as "verbal") and visual (previously "nonverbal") memory, immediate and delayed recall, single-trial vs. multitrial learning, and percent retention composites in each domain are now provided. Recognition memory procedures were also added to several of the WMS-III subtests. The subtests of the WMS-III include: Information and Orientation, Logical Memory, Verbal Paired Associates, Word Lists, Faces, Family Pictures, Visual Reproduction, Letter–Number Sequencing, Spatial Span, Digit Span, and Mental Control. Whereas this is a lengthy list of measures, five of the subtests (Information and Orientation, Word Lists, Visual Reproduction, Mental Control, and Digit Span) are supplemental or optional and do not contribute to the primary index scores. From various combinations of the core subtests, the primary index scores can be derived: Auditory Immediate, Visual Immediate, Immediate (combined), Auditory Delayed, Visual Delayed, Auditory Recognition Delayed, General Memory, and Working Memory.

The WMS-III is obviously comprehensive in its scope, now including aspects of a variety of memory assessment stimuli and procedures. It is lengthy and overlaps with some other standard memory tests in common use, but contains some interesting new procedures based on research and clinical experience in neuropsychology. Because of its recent release, studies regarding its ultimate clinical utility in various settings and populations will be needed, in addition to the development of procedures for deriving short forms and estimating memory index scores. Perhaps even more so than with the WMS-R, it is anticipated that when administration of the entire test is not feasible, many clinicians will routinely utilize selected subtests of the WMS-III to fit their particular memory assessment needs.

4.11.4.8.4 Verbal memory tests

(i) California Verbal Learning Test (CVLT)

This is a 16-item word list-learning task that contains items from four semantic categories (Delis, Kramer, Kaplan, & Ober, 1987). The list is presented five times to subjects, in the same order, which allows for not only an assessment of learning, but of primacy-recency recall effects. The CVLT was developed with principles of cognitive neuroscience and clinical memory disorders in mind, and provides a quantitative assessment of a wide variety of qualitative features of memory performance. It has been shown to be reliable (Paolo, Troster, & Ryan, 1997) and clinically useful in a variety of clinical populations, particularly in the differential diagnostic assessment of memory disorders (Cullum, Filley, & Kozora, 1995; Peavy et al., 1994).

After the fifth presentation of the word list, an interference list is presented to permit an examination of the effects of interference on recall. Next, free recall of the initial word list is examined, followed by cued recall that involves the presentation of semantic categories for the words (e.g., "Tell me all the items that were fruits"). Long delay free recall is examined following a 20-minute delay. This is immediately followed by another series of cued recall trials, and finally, a recognition trial wherein a longer list of items containing target items as well as distractors is presented, and subjects must simply indicate "yes" or "no" whether or not these items appeared in the originally presented list. As noted, the CVLT provides for a quantified assessment of a variety of qualitative aspects of verbal learning and memory, and scoring software is available to provide normative reference scores for a host of verbal learning and memory indices. An alternate form of the CVLT has been developed that has shown good correlations with the original version (Delis et al., 1991), and a revised CVLT is in preparation in 1998. A nine-item dementia version of the CVLT has also been derived for use in more impaired populations (Libon, Mattson, et al., 1996).

(ii) Hopkins Verbal Learning Test (HVLT)

This test was developed to provide an abbreviated assessment of word list-learning and memory (Brandt, 1991). It is particularly well suited for more impaired patients who might not be able to complete measures such as the CVLT. A list of 12 items from three semantic categories is presented across three trials, followed by recognition testing. A modification of the original HVLT provides for an assessment of delayed recall prior to recognition in order to assess forgetting over time. A unique aspect of the HVLT is that it includes six alternate forms, thereby reducing practice effects and making it a good choice in serial assessment situations.

(iii) Logical Memory (WMS, WMS-R, WMS-III)

This is the classic story learning and memory test that is one of the most widely used clinical indices of memory function. It is a measure of the ability to learn and retain new structured verbal information. The original WMS included two stories that were read to patients, followed by an assessment of immediate recall. The WMS-R updated the stories, norms, and scoring procedures, and importantly, added a delayed recall trial. Each of the WMS-R stories contains 25 bits of information, and a standard 30-minute delayed recall procedure provides for a ready assessment of forgetting rates. The WMS-III version includes an initial story that is administered in standard fashion (i.e., one trial, followed by immediate and then delayed recall), and a second story that is repeated in order to assess the effects of learning on storage and retrieval of material.

Patients' responses should be written down verbatim in order to glean additional qualitative information, and to allow for cross-checking of scoring. Scoring for Logical Memory is done largely based upon identical or almost-identical recall of the story material, although several scoring procedures allow partial credits to be assigned for close approximations, and the WMS-III version also incorporates scores for thematic units or gist. Logical Memory has been shown to be highly useful in the assessment of a wide array of memory disorders and senstive to left hippocampal damage in particular (Sass et al., 1992).

4.11.4.8.5 Nonverbal memory tests

(i) Rey–Osterrieth complex figure

This is a very popular measure of nonverbal memory and is described and presented in several sources (e.g., Corwin & Bylsma, 1993; Lezak, 1995; Rey, 1941; Spreen & Strauss, 1998). It consists of a complex figure made up of various subcomponents. Administration procedures vary somewhat (see Meyers & Meyers, 1995), although in one of the more common administrations the task requires patients to first copy the figure, and then immediately upon its removal (and without instructions to remember the figure), reproduce it from memory. Fifteen minutes later, delayed recall is assessed. Recognition procedures have also been developed and used in some settings. Several scoring systems for the test have been developed (e.g., see Lezak, 1995; Loring, Martin, Meador, & Lee, 1990), although qualitative interpretation of patients' reproductions often provide much more detailed information than quantitative scores alone. The Boston scoring approach (Stern et al., 1994) to the Rey–Osterrieth attempts to provide a quantitative assessment of many of the qualitative features of the figure.

(ii) Visual Reproduction (WMS, WMS-R, WMS-III)

This is one of the most commonly used measures of visual or nonverbal memory, and is often used in conjunction with its verbal counterpart, Logical Memory, even when the WMS are not used in their entirety. Although each version of the WMS contains somewhat different stimulus figures (only two of the original WMS figures have been included in both the WMS-R and WMS-III, and Visual Reproduction is optional in the latest rendition), the administration procedures are similar. It consists of the presentation of several cards with geometric designs on each. Each card is presented to subjects for 10 seconds, and after each is removed from view, immediate recall is assessed by having the subject draw the design from memory. Following a delay of 20–30 minutes (25–35 minutes in the WMS-III), subjects are asked to reproduce the designs again from memory.

As noted, Visual Reproduction has long been used as a measure of nonverbal memory. While some literature indicates that the test does not readily lend itself to localization of cerebral dysfunction in large groups and may be insensitive to nondominant temporal lobe resection (Barr et al., 1997; Naugle et al., 1993), it can be useful in some individual cases as there may be a tendency for patients with right temporal lobe dysfunction to do more poorly (Chelune & Bornstein, 1988). Furthermore, it can be of assistance in providing a more detailed examination of memory function beyond the assessment of learning and memory for words and stories.

(iii) Warrington Recognition Memory Test (RMT)

This is a test of word and face recognition that allows for a comparison between basic verbal and nonverbal abilities (Warrington, 1984). First, a series of 50 single words is presented in a booklet, followed by yes/no recognition testing. The same procedure is performed for a series of 50 black and white pictures of unfamiliar male faces. While some studies of patients with lateralized brain damage have demonstrated the expected associations between left hemisphere/word recognition and right hemisphere/face recognition deficits (Warrington, 1984), this relationship does not always hold true (Naugle, Chelune, Schuster, Luders, & Comair, 1994), and the test is perhaps best used as a supplemental test of memory in conjunction with more primary measures. In clinical practice, many patients seem to have more difficulty with the facial recognition portion of the RMT, and the association between words and faces with left vs. right hemisphere dysfunction is variable.

4.11.4.9 Motor and Sensory Function

A variety of clinical procedures have been developed in neuropsychology and behavioral neurology to examine simple and complex motor functions. These range in complexity, degree of standardization, and level of knowledge required for appropriate interpretation/analysis. At a most basic observational level, how a patient walks and moves during an evaluation can provide useful information regarding aspects of their motor functioning. Evidence of unilateral motor weakness, tremor, or other unusual movements may reflect a neurological condition or even suggest a focal cerebral deficit. These observations can also spur the astute observer to inquire more carefully about specific symptoms and may help guide the neuropsychological evaluation in terms of test selection. To take an obvious example, the patient presenting with unilateral left-sided motor weakness (e.g., foot drag and/or decreased limb mobility) should undergo careful inquiry about their symptoms, and depending upon the situation, the clinician may wish to follow up on this observation by including appropriate sensory, motor, and cognitive tasks in his/her evaluation in order to assess abilities associated with right hemisphere function.

The primary motor and sensory areas of the cortex, as well as their multiple ascending and descending fiber tracts, are well known and charted. It must be kept in mind, however, that sensory and motor regions have significant overlap in terms of cortical surface representation, and deficits are often multimodal in nature, with more complex integrative functions having a broader distribution. In addition to the assessment of two-point discrimination and simple touch, for example, more subtle cortical deficits may be detectable by the use of double simultaneous stimulation techniques. These are typically conducted in the visual, auditory, and haptic modalities, and a variety of simple quantifiable procedures can be used. Double simultaneous stimulation in the tactile modality involves repeated trials of unilateral light touch to the back of either hand, interspersed with bilateral touch. Subjects are asked to indicate which hand was touched. Tactile extinctions or suppressions occur when one side is not perceived, and if consistent, this may suggest contralateral parietal lobe dysfunction.

Basic motor function can be quantified using various techniques and instruments, depending upon the degree of detail that is desired about a given function. Simple finger tapping speed can be assessed crudely by having the patient tap their first finger to their thumb as quickly as possible, first with the dominant, then non-dominant hands. Grip strength can be assessed by having the patient squeeze the examiner's fingers, but this technique tends to be extremely crude and is better left to a dynamometer when accurate information is desired. Fine motor dexterity can be assessed using a variety of procedures, including having the patient touch each finger consecutively to their thumb in rapid, repetitive fashion. Stereognosis can be readily examined by having the patient name objects placed in their hand without the aid of vision.

Whatever motor or sensory assessment task used, is important to note that noncortical or noncentral nervous system (non-CNS) (i.e., subcortical, spinal, peripheral) damage can produce deficits in motor and/or sensory function. Furthermore, other factors such as inattention or impairments in concentration or memory may result in poor scores or errors on sensorimotor tasks. In the absence of neuropathology, gross errors or variable responses should alert the clinician to the possibility of poor effort. In practice, motor and sensory deficits tend to be consistent, such that repeated trials later in the examination should yield similar results. Interpretation of results from these tests should always begin with these considerations in mind.

4.11.4.9.1 Psychometric measures of motor and sensory function

(i) Finger Tapping Test

This test is a simple assessment of index finger tapping speed using a mechanical tapping key device (Reitan & Wolfson, 1993). Patients are instructed to tap using their dominant hand index finger as fast as possible, and the number of taps performed within a series of 10-second intervals is recorded and averaged. These results are compared with similar scores from the nondominant hand. Most right-handed individuals tend to show approximately a 10% dominant hand superiority. Gross aberrations from this may reflect contralateral anterior cerebral dysfunction, although it is important to note that arthritis or peripheral injuries to the brachial plexus, arm, hand, or fingers can have profound effects on this test and must be carefully ruled out before cerebral implications are made.

(ii) Grooved Pegboard

This is a test of fine motor dexterity that requires subjects to pick up small (one inch) metal pegs that are rounded on one side and squared on the other (Kløve, 1965). The task is to pick them up one at a time and place them in similarly shaped holes on the test platform as quickly as possible. First, the dominant hand is tested, followed by the nondominant hand. The task requires fine motor coordination and speed.

(iii) Hand dynamometer

Various manufacturers provide grip strength meters to assess basic hand strength. This is a device that requires patients to simply squeeze a handle as hard as they can, and the amount of force they exert is indicated in pounds or kilograms on the instrument. Two or three trials are usually administered with the dominant and nondominant hands. Dominant hand grip strength usually tends to be approximately 10% stronger than nondominant in most right-handed individuals.

(iv) Sensory–Perceptual Examination (SPE)

This test is included in the HRB, but is often used apart from this battery in its entirety or in portions (Reitan & Wolfson, 1985). The basic functions assessed by the SPE include finger gnosis, graphesthesia, stereognosis, and basic sensation and extinctions to simple stimulation and double simultaneous stimulation in the visual, auditory, and tactile modalities. It essentially represents a quantified approach to some of the sensory testing often performed in the traditional neurological examination. In the absence of peripheral damage factors, arthritis, severe cerebral dysfunction, or prominent attentional difficulties (which can make the interpretation of patient responses more difficult), deficits associated with these various tasks may suggest some degree of impairment of the sensory cortex and/or associated pathways.

4.11.4.10 Assessment of Motivation

The sensitivity and clinical utility of neuropsychological measures is largely dependent upon the cooperation and effort of the patient being evaluated. Poor effort can result in artificially low or otherwise abnormal neuropsychological test scores, and the clinician must always be alert to this potential confound during test administration and interpretation. Careful analysis of levels and patterns of neuropsychological performance in relation to the disorder in question is critical (i.e., "Do the results make sense given what has happened to the patient?). For example, the patient with an uncomplicated mild traumatic brain injury should not demonstrate severe, widespread neuropsychological deficits, and this finding in such a case should raise questions regarding levels of motivation and effort. Furthermore, as serial testing frequently occurs within the context of forensic neuropsychological evaluations, the examination of consistency of scores within and across test sessions can be a very good source of information regarding the likelihood of invalidity or unreliability of results (Cullum, Heaton, & Grant, 1991; Reitan & Wolfson, 1997).

The issue of malingering in relation to neuropsychological assessment has been reviewed in several excellent sources (e.g., Franzen, Iverson, & McCracken, 1990; Nies & Sweet, 1994). Suspected malingering or willful distortion/exaggeration of deficits continues to pose challenges in various clinical settings. Along these lines, a number of specialized tests and procedures have been developed to help detect exaggerated or feigned deficits. Some of these involve the administration of simple tasks that are presented as being difficult (e.g., Rey's 15-item test; Lezak, 1995). Others that show promise are based upon the time to complete shorter or less difficult vs. longer tasks (e.g., the Dot Counting Test; Lezak, 1995; Rey, 1941). Another technique involves the comparison of unusual patterns of performance with results known to be associated with a particular deficit or disorder (e.g., Brandt, 1988). Perhaps the most popular approach has been to utilize forced-choice recognition testing (Guilmette, Hart, & Giuliano, 1993; Hiscock & Hiscock, 1989), which relies upon probability theory by identifying performances that fall below a chance level (e.g., the Portland Digit Recognition Test; Binder, 1993).

The detection of malingering poses a complex challenge to clinicians, particularly as a variety of psychological and situational factors (e.g., gain issues) may further complicate the diagnostic picture. While it is difficult to definitively prove malingering in a particular case, the existing research suggests that it is often possible to detect evidence of malingering, although this requires skillful and deliberate inquiry by the clinician.

As with diagnosis, the clinical history can prove invaluable in establishing the likelihood of malingering. Consistency of reporting is important, and information from various sources can be compared, including clinical interview data and reports from the patient to other professionals. The consistency or "fit" between neuropsychological test results and reports of everyday functioning can also be highly useful. For example, the patient who performs in the severely impaired range on formal memory testing should demonstrate difficulties with memory in their everyday functioning. Likewise, neuropsychological test data obtained from the patient who has gross difficulty with coordination, sequencing, memory, and reaction times who rides skillfully away on his/her motorcycle following the evaluation should be carefully scrutinized.

As indicated by Nies and Sweet in their review of the literature, "Note that, at present, multiple measures and methodologies are needed, in that no single measure or methodology has proven sufficient to date" (1994, p. 544). They recommend some of the following strategies that may assist in the clinical detection of malingering: (i) use specific tests of malingering as outlined above, (ii) evaluate patterns on clinical neuropsychological tests where below-chance performances can be assessed, (iii) examine unusual or aberrant test results, (iv) examine consistency of test scores within and across measures and test sessions, (v) obtain independent information regarding a patient's reports of their everyday functioning, and (vi) obtain a detailed clinical history and carefully examine the information provided, both in terms of accuracy and consistency.

4.11.4.11 Personality and Emotional Functioning

Changes in the functional integrity of brain systems can result in alterations in emotional reactivity (e.g., lability) and personality. In some cases, subtle changes in behavior and personality may represent the primary or earliest harbingers of brain dysfunction. The evaluation of emotional or personality change associated with neurological disease or damage poses a complex set of challenges. Damage to the frontal and prefrontal cortex can be particularly associated with personality change. This may present variably as decreased responsivity (e.g., apathy or amotivation) or increased responsivity (e.g., hypomania, increased or indiscrimant drives), depending upon the primary site of damage. In cases of lateralized brain dysfunction, left hemisphere lesions (particularly more anterior) have been shown to be associated with depressive symptomatology, while lesions of the right hemisphere tend to be more frequently associated with varying degrees of unawareness or denial (anosognosia) of deficit (e.g., see Lacritz & Cullum, 1998).

Right hemisphere damage can also result in aprosodia, which refers to the impaired ability to communicate meaning using intonations and inflections during speech (emotional language). Some data suggest that the aprosodic syndromes secondary to right hemisphere dysfunction parallel the aphasias (Ross, 1985), with anterior right hemisphere lesions being more associated with expressive dysprosody, and more posterior lesions associated with receptive dysprosody. Expressive prosody testing can be readily accomplished by asking the patient pretend to be an actor and say a neutral sentence such as "I am going to the movie" using different affective intonations (happy, sad, angry, indifferent). Receptive prosody can be assessed by the examiner (while outside of the patient's view) saying a sentence in different tones of voice and having the patient indicate if the examiner sounded happy, sad, angry, indifferent, etc. The patient with expressive dysprosody will generally sound monotone and be unable to alter the affective tone of their voice across test conditions aside from perhaps becoming louder or softer at times. The patient with receptive dysprosody will be able to say the sentence with variable affective intonations, but will have difficulty guessing the affective valence of the examiner's sentences.

The issue of changes in emotional functioning following brain damage represents a complex biopsychosocial interaction that merits careful investigation, since multiple factors may be involved. Obviously, an insult to the brain can have a direct neurobiological effect upon the way in which information and affect is processed. However, individual psychological reactions to changes in cognitive and/or physical functioning are also commonly seen. To help establish whether neurobiologically-induced changes have occurred, the clinician must be careful to obtain information regarding patients' premorbid functioning from family members or others who know the patient, as well as patients themselves. Defensiveness or unawareness on the part of the patient and/or family may exist, and it must be kept in mind that the clinician may be hearing a biased picture of the situation. The issue of secondary gain and malingering as discussed above must also be considered, particularly in litigation situations. Finally, the potential effects of pre-existing psychopathology should be examined, and psychiatric and/or more detailed psychological evaluation may be useful along these lines. Direct questioning about symptoms and behavioral changes obviously may be productive, although in some instances, the line of inquiry must be more subtle, requiring indirect probing of evidence for personality/emotional changes. Rephrasing questions and asking about related symptoms in a variety of contexts may also be a useful means of not only verifying information, but in some cases, uncovering important data.

Formal psychological assessment in patients with neurological disorders requires some adjustments to standard interpretations, insofar as the endorsement of certain symptoms may simply relate to the neurological condition rather than implying psychopathology. For example, patients with neurologic disease often demonstrate clinical elevations on the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) that should not be necessarily attributed to psychological disturbance. Scale 8 in particular contains a number of items dealing with unusual symptoms, and scales 1 and 3 relate to aspects of physical functioning which may be endorsed by neurological patients due to their physical status, in the absence of psychopathology. Table 7 presents some of the more commonly used measures of psychological functioning within the context of the neuropsychological evaluation.

4.11.4.12 Test Selection Issues

As noted, specialized core batteries of tests are often assembled by neuropsychologists for specific populations. Test selection is based on training and experience in combination with information obtained from the relevant literature. Table 8 presents an example of a test battery designed to assess dementia (both in terms of early detection as well as assistance with differential diagnosis and staging of disease). Note that individual measures can readily be added or dropped (i.e., a "stepdown battery") from the "core" set of tests, depending upon specific patient needs and clinical questions.

An example of a modification to this battery in the case of a high functioning business executive referred for evaluation secondary to suspected incipient Alzheimer's disease might include the following: administration of a complete WAIS-III to obtain a more precise assessment of current intellectual functioning and allow for analysis of subtest patterns; possible omission of the DRS since it may not be sufficiently sensitive to subtle deficits in such an individual in the early stages of dementia; addition of the category test to provide a more challenging evaluation of higher-order cognitive abilities than the WCST; substitution of the Ravens Advanced Matrices for the coloured version, as the latter would likely be too simplistic to be of much value in such a case; administration of a complete WMS-III to provide a more thorough examination of memory function.

Alternatively, the test battery might be dramatically altered in the case of a patient with known dementia who is being followed to track their rate of cognitive decline (or perhaps to assess for any positive effects of cognitive enhancing medications). As a more extreme example, if an individual presents with clear evidence of severe dementia during clinical interview (or if the patient had a previous MMSE score of 10), it may suffice to administer the DRS and obtain only a brief screening assessment of cognitive domains (e.g., by administering all or parts of the CERAD neuropsychological test battery). In such a case, a brief neuropsychological examination may nevertheless be considered "comprehensive" insofar as a range of abilities is assessed, and the addition of multiple complex measures may actually yield little additional neurobehavioral data, depending on the individual patient and referral questions.

4.11.4.13 Relationships Between Neuropsychometry and the Behavioral Geography of the Brain

Neuropsychological procedures, like the neurological examination, are designed to provide information about the integrity of human brain function. While these measures are sensitive to impaired cognition and may provide information regarding lateralized or focal dysfunction, it

Table 7 Common measures of psychological and emotional functioning.

Minnesota Multiphasic Personality Inventory-2 (MMPI-2)	Psychopathology/emotional status
Personality Assessment Inventory (PAI)	Psychopathology/emotional function
Millon Clinical Multiaxial Inventory (MCMI)	Personality styles, psychopathology
Beck Depression Inventory (BDI)	Depression
Inventory of Depressive Symptomatology (IDS)	Depression
Profile of Mood States (POMS)	Brief review of psychiatric symptoms
Symptom Checklist-90 (SCL-90)	Brief review of physical and psychiatric symptoms

Table 8 Sample test battery for the evaluation of dementia.

Global cognitive functioning
  - Dementia Rating Scale
  - WAIS-III/WAIS-R IQ or IQ estimate (e.g., based on Vocabulary and Block Design)
  - NART-R estimated premorbid IQ

Reasoning/Cognitive flexibility
  - Wisconsin Card Sorting Test
  - Similarities and proverbs testing (WAIS-III)
  - Trail Making Test, Part B

Language
  - WAIS-III Vocabulary
  - Boston Naming Test
  - Verbal fluency (letter and category, e.g., FAS, animals)
  - Token Test and/or Comprehension subtest from BDAE

Visuospatial skills
  - WAIS-III Block Design
  - Clock drawing
  - Rey–Osterrieth Complex Figure (copy)

Attention/concentration
  - WAIS-III Digit Span (forward)
  - Trail Making Test, Part A

Learning and Memory
  - California Verbal Learning Test
  - Wechsler Memory Scale-3 (WMS-III) or Wechsler Memory Scale-Revised (WMS-R) or portions thereof (e.g., Logical Memory and Visual Reproduction)
  - Rey–Osterrieth Complex Figure (immediate and delayed recall)

Motor functioning
  - Finger tapping test
  - Rapid Alternating Movements/Luria three-step

should be kept in mind that the neuroanatomical specificity of most of the tests is limited (Dodrill, 1998). Furthermore, while the frontal, temporal, parietal, and occipital cortices subserve specific functions to some degree, the amount of overlapping functional representations and inter-relationships cannot be underscored. It is worth recalling that even "primary" motor and sensory regions of the cortex have overlapping cellular representations and functions to some degree. Thus, the extent to which various cognitive functions are said to be "localized" is somewhat relative, although a number of functional neuroanatomic correlations exist with various measures. Higher cognitive functions in particular tend to defy localization, although frontal systems (particularly prefrontal cortices) tend to be heavily involved in the many abilities associated with executive functioning (e.g., planning, reasoning, judgment, insight) and personality. Limbic structures of the temporal lobes play a predominant role in learning and memory for new information, with verbal memory skills being strongly associated with left hemisphere (specifically temporohippocampal) functions in most individuals. Although less well supported, association is also often seen between nonverbal memory abilities and nondominant temporal lobe functioning. The limbic system is also intimately associated with aspects of emotional processing, and links between affective memory and limbic functioning have been shown. While functional neuroanatomic distinctions exist (by lobe as well as in the anterior–posterior and lateral planes), the myriad interconnections that exist between these areas and other cortical and subcortical systems indicate that various brain functions may be disrupted when specific circuits or systems are damaged, even when the cortical region known to be largely responsible for a given function may appear to be intact. Thus, a careful probing of multiple aspects of brain–behavior relationships is required to provide a thorough assessment of function.

4.11.4.14 Training in Neuropsychology

Because of the complexities inherent in the neurobehavioral assessment of human brain function, specialized training is needed for the clinical neuropsychologist. Neuropsychologists must have a firm understanding of basic brain organization and function, and need to be familiar with neurological disorders and neuropathology as well as their myriad behavioral sequelae. As such, specific knowledge bases must be mastered that go beyond the traditional training of the doctoral degree in psychology.

Several documents relevant to training and practice in the specialty of clinical neuropsychology have been published over the years (e.g., Adams & Rourke, 1992; Eubanks, 1997; Reports of the INS-Division 40 Task Force on Education, Accreditation, and Credentialing, 1987), although the most comprehensive and far-reaching proviso to date was published in 1997. The Houston Conference on Specialty Training and Education in Neuropsychology was held in September 1997 and outlines recommended training and education guidelines for the future in clinical neuropsychology (Hannay et al., 1998). For this conference, neuropsychologists representing various backgrounds, employment settings, and organizations were selected from applications across the USA and Canada and invited to participate. One of the goals of the Houston Conference was to develop the guidelines for an integrated model of education and training in clinical neuropsychology, and this includes the following generic definition of a clinical neuropsychologist:

> A clinical neuropsychologist is a professional psychologist trained in the science of brain–behavior relationships. The clinical neuropsychologist specializes in the application of assessment and intervention principles based on the scientific study of human behavior across the lifespan as it relates to normal and abnormal functioning of the central nervous system. (p. 161)

The recommendations for coursework, training, and skills are provided in some detail, including a model of integrated education across the doctoral, internship, and postdoctoral or residency levels. In addition to core courses in clinical psychology (e.g., psychopathology, assessment, ethics), coursework in areas pertaining specifically to brain–behavior relationships are recommended, including neuroanatomy, psychopharmacology, and various aspects of neuropsychology *per se*. It is noted in the Policy Statement of the Houston Conference that the proposed guidelines were not intended to be applied retroactively or to those currently in training at the time of the conference and proceedings, but rather, to serve as recommendations for future education and training in clinical neuropsychology. Whereas the specific functions of neuropsychologists vary depending upon setting, the following seven professional activities were put forth as being important for the clinical neuropsychologist: assessment, intervention, consultation, supervision, research and inquiry, consumer protection, and professional development. A postdoctoral residency of the equivalent of two years full time experience is included in these recommendations. Some of the exit criteria for the postdoctoral residency include demonstration of advanced skills in neuropsychology, eligibility for state or provincial licensure, and eligibility for board certification in clinical neuropsychology.

4.11.4.15 Challenges for Neuropsychological Assessment

The neuropsychological evaluation represents the most sensitive existing means by which to assess the functional integrity of the human brain. Modern structural imaging provides us with wonderfully detailed images of intracranial contents, but even knowing that an abnormality exists in a given region cannot provide much insight into how that patient is able to function and process information in day-to-day life. Functional imaging has seen major advancements in recent years and is able to indicate areas of relative dysfunction—but this, too, cannot indicate what specific cognitive abilities are impaired, or to what extent. Such techniques also offer little or no insight into how to help brain-injured patients adapt and better compensate for their altered cognitive processing, as this is the purview of clinical neuropsychology.

Neuropsychological assessment is faced with the ongoing challenge of improving diagnostic and prognostic procedures and integrating findings from clinical neuropsychology, cognitive psychology, and neuroscience into assessment tools that can provide increasingly detailed examinations of some of the intricacies of human brain function. Many of the neuropsychological tests in common use in the 1990s were developed years or decades ago, and even though some procedures are "tried and true" and continue to provide important neurodiagnostic and neurodescriptive information, the field must strive to keep up with the rapid advances being made in neuroimaging and neuroscience and be open to incorporating this new information into assessment procedures.

4.12.1 INTRODUCTION

Consider a hypothetical clinician who is both well trained and well informed about available personality tests. In her daily practice, she employs a range of assessment instruments (singly or in combination) to address the range of diagnostic issues posed by her clients. When "thought disorder" is suspected, she might occasionally administer a Rorschach and from most clients she will obtain a case history. Her clients themselves may be asked to fill out the NEO-Personality Inventory to clarify dimensions of normal personality functioning or the Minnesota Multiphasic Personality Inventory-Revised (MMPI-2) to assess gross abnormality. She might also routinely administer the Interpersonal Adjective Scales to assess the character and quality of clients' interpersonal relationships.

Like many of her colleagues, our clinician may describe her theoretical orientation as "eclectic" and indeed that is what she appears to be. But she is also, perhaps unknowingly, operating within larger historical contexts of assumptions and beliefs that may include traditions of thought as diverse as psychoanalysis, psychobiography, psychometrics, empirical realism, and symbolic interactionism (respectively for the tests just mentioned). We will refer to such contexts as different "traditions" of personality assessment, by which we mean the background of a set of unquestioned beliefs or orienting attitudes within and against which personality tests are administered and interpreted.

The traditions that will be considered in this chapter are referred to as psychodynamic, personological, multivariate, empirical, and interpersonal. Such traditions are related, but *not* equivalent, to certain theories of personality (Hall & Lindzey, 1978) and psychopathology (Millon, 1969). Similarly, these traditions are related, but *not* equivalent, to certain kinds of personality tests. Thus, the MMPI has been associated with a distinctive philosophy of science (empirical realism) rather than with a particular theory of psychopathology. The Rorschach test and the Wechsler scales have figured prominently within the ego psychological perspective of the psychodynamic tradition, although both tests were constructed for quite different purposes.

We believe that these traditions reflect different and potentially useful ways of viewing the entire psychodiagnostic enterprise. We also believe that these traditions have contributed to more or less invisible barriers to communication being erected among clinicians who work, knowingly or not, within them. This state of affairs is unfortunate because "membership" in a tradition, as it were, is mainly determined by where one went to graduate school, with whom one studied, and the particular clinical setting in which one finds oneself operating. Further, we are convinced that, at the present time, there are some remarkably similar ideas being advocated about the nature of personality and its assessment among those working within several different traditions, and that recognition of these commonalties might advance the field as a whole (see Wiggins, in press).

We would venture to suggest that most readers will have familiarity with a few of these traditions, but not with some of the others. For example, those intimately familiar with the psychodynamic tradition are less likely to be familiar with the multivariate and empirical traditions, and vice versa. Those who are fond of obtaining life history data from interviews may not be fully aware of the rich history of the personological tradition nor of the exciting recent developments that have occurred within that tradition. And many may not be aware that the interpersonal tradition has fostered a strong "underground movement" within clinical psychology for many decades.

4.12.2 PSYCHODYNAMIC TRADITION

4.12.2.1 Historical Background

David Rapaport (1911–1960) was a major systematist of psychoanalytic theory, the originator of a now standard psychodiagnostic test battery, and a highly influential mentor of the principal architects of the psychodynamic tradition in personality assessment. After receiving his PhD from the Royal Hungarian University, he emigrated to the USA in 1938 and shortly thereafter joined the staff of the Menninger Clinic where he eventually became chief psychologist and head of the research department. During and shortly after World War II, the results of an extensive program of collaborative research were summarized in a two-volume *Manual of diagnostic psychological testing* (Rapaport, 1944–46) that eventually "revolutionized clinical psychology and influenced clinical psychologists the world over" (Gill & Klein, 1967, p. 18).

Rapaport moved to the Austin Riggs Center in 1948 and continued his extensive collaborations with colleagues at institutions such as the Menninger Foundation, Yale University Department of Psychiatry, and the Research Center for Mental Health at New York University. Speaking collectively for workers at these and other institutions, Roy Schafer (1967) observed, "All of us are working within the psychoanalytic psychodiagnostic tradition crystallized by David Rapaport" (p. 2).

4.12.2.2 Conceptual Framework

It is difficult to make a coherent set of distinctions among the many "psychodynamic" theories that have been proposed as alternatives to Freud's classical psychoanalytic theory (Westen, 1990). It would seem to be generally true however that since, and even before, Freud's death, there has been an increased emphasis on the autonomous and adaptive functions of the ego and on the internal representation of self and others within the ego domain. The aspect of classical psychoanalysis that has been de-emphasized, or even abandoned by some, is the proposition that personality and its development are largely determined by unconscious libidinal and aggressive drives.

Rapaport (1960) must be counted among the most rigorous systematists of classical psychoanalytic theory and he was also a major contributor to the alternative perspective known as "ego psychology." In both his theoretical and assessment work, his principal interest was in thought processes and their course of development from drive-oriented to reality-oriented processes. In this context, Hartmann's (1939) concept of the independence (from drive) of the ego and its role in fostering active processes of adaptation were appealing to him, as was Erikson's (1950) emphasis on the cultural and historical contexts in which the ego develops. Rapaport (1960) developed and expanded the metaconcept of structure which he felt was the "prime requisite for progress toward dimensional quantification" (p. 98) and which he applied broadly to many aspects of psychological functioning and cognitive organization (see Gill & Klein, 1967).

The generally increased emphasis upon ego functions in postclassical psychoanalysis was also reflected in the currently important psychodynamic alternative of object relations theory. Proponents of this view challenged the classical idea that cathexes of external "objects" (including persons) served mainly as vehicles through which instinctual energies were discharged. Instead, it was postulated that early interactions with significant others ("objects") led to internalized representations of both others (Jacobson, 1954) and self (Kohut, 1971) that serve as "internal working models" (Bowlby, 1973) for later interpersonal relationships. From this perspective, the person is, from birth (Main, Kaplan, & Cassidy, 1985), an object seeker (Fairbain, 1952) who establishes a "gratifying involvement" with other persons (Behrends & Blatt, 1985).

The shift in emphasis within psychoanalytic theory from drives to internalized representations has been accompanied by a corresponding shift in rationales for personality assessment, as exemplified by the ego-psychological approach of Allison, Blatt, and Zimet (1968) and the object-relations approach of Blatt and Lerner (1983).

4.12.2.3 Assessment Instruments

Prior to Rapaport's influential contributions in the 1940s, assessment psychologists were primarily technicians who administered IQ tests. Since that time, they have become clinicians who administer batteries of both structured and projective tests of personality and cognition. The multitest battery was advocated in view of the apparent complexity of personality and cognition and their interrelated functions, as well as for the purpose of gathering normative data that would shed light on those complexities (Rapaport, Gill, & Schafer, 1946). At Menninger, the composition of the battery reflected judgments regarding the potential of each instrument to yield measures that might be interpreted within the ego psychological framework of Rapaport and his associates.

The projective component of the original Menninger battery included the Rorschach Test (Rorschach, 1921), the Thematic Apperception Test (TAT; Morgan & Murray, 1935), and a locally constructed Word Association Test. The nonprojective component included the Bellevue Scale (Wechsler, 1941), the Babcock Test of mental efficiency (Babcock, 1933), the Sorting Test of concept formation (Goldstein & Scheerer, 1941), and the Hanfmann–Kasanin test of concept formation (Hanfmann & Kasanin, 1937). As this test battery evolved over a 20-year period, the Rorschach, TAT, and WAIS (Wechsler, 1958) became the more or less standard core of the psychodynamic test battery (e.g., Allison et al., 1968).

4.12.2.4 Interpretive Principles

The vast literature on interpretive principles associated with the psychodynamic paradigm defies easy summarization. Rapaport's theoretical work (e.g., Gill, 1967) and the writings of those whom he influenced (e.g., Holt, 1967) are, understandably, highly technical in nature. Of greater help to the clinician are the case summaries (Allison et al., 1968; Prelinger & Zimet, 1964; Rapaport et al., 1946; Schafer, 1948) and the individual treatments of the Rorschach (Schafer, 1954), TAT (Holt, 1951), and WAIS (Blatt & Allison, 1981). The following statements regarding the projective hypothesis, levels of functioning, and psychological adjustment are meant only to convey some of the flavor of three, among many, important interpretive principles.

4.12.2.4.1 Projective hypothesis

The projective hypothesis states that "All behavior manifestations of the human being, including the least and the most significant, are revealing and expressive of his personality, by which we mean that individual principle of which he is the carrier" (Rapaport, 1942, p. 92). Thus, people's possessions—clothes, automobiles, furniture—are expressive of their personalities and reflect single acts of choice; in their totality, they reflect the organization of such choices. Responses to the ambiguous stimuli of projective tests may also be thought of in terms of "choice," although such choices are much less conscious or volitional in nature. Thus, responses to a Rorschach inkblot may be thought of as reflecting "choices" between forms, colors, shadings, and so forth, to which a subject imparts meaning through organization. Responses to a TAT card also involve both choice (e.g., which figure to identify with) and organization (e.g., sequence of events). Responses to intelligence and concept formation tests involving choice and organizational processes may be used as "nonprojective tests of personality," given an adequate theory of "functions underlying the reactions and achievements on these tests" (Rapaport, 1946, p. 228).

4.12.2.4.2 Levels of functioning

The psychoanalytic model of primary (pleasure principle) and secondary (reality principle) modes of thought is meant to account for both a developmental sequence and characteristics of the mature adult (Rapaport, 1951). Consequently, there is a continuum of adult psychological functioning that may be assessed with an appropriate battery of tests.

> This continuum ranges from functioning in situations which put a premium on highly logical, reality-oriented secondary modes of thought (WAIS) to those which allow for more personal, less conventionally constrained thinking (TAT) and finally those which allow for considerably novel, personalized, and regressive modes of thinking (Rorschach). (Allison et al., 1968, p. vii)

Assessment of level of functioning has been greatly facilitated by Holt's innovative procedures for assessing primary and secondary process in the Rorschach (Holt & Havel, 1960).

4.12.2.4.3 Psychological adjustment

The Rorschach, TAT, and WAIS may be employed to assess both adaptive capacities and impairments in psychological functioning and to identify the functions impaired in different psychiatric diagnostic groups. Adjustment and maladjustment may be assessed with reference to the following postulated sequence:

> Certain patterns of defense mechanisms are adopted and these determine specific strengths and weaknesses in psychological functioning which then become characteristic of the adjustment of the personality; with the onset of maladjustment, an exaggeration or breakdown in these strengths and weaknesses characteristic for that maladjustment occurs which can be measured; this leads to a diagnostic differentiation. (Rapaport, Menninger, & Schafer 1947, p. 249)

4.12.2.5 Applications and Current Status

Since the late 1960s, theory and method within the psychodynamic paradigm of personality assessment have evolved into an object relations perspective that is highly compatible with contemporary formulations of social cognition, information processing, attachment research, and ego development (see Westen, 1990). Sidney Blatt and his associates at Yale have been primarily responsible for this paradigm shift. From the early 1950s until his untimely death in 1960, Rapaport contributed to the development of ego psychology and its application to personality assessment; since the early 1970s, Blatt has contributed to the development of object relations theory and its application to current personality assessment methods.

"The study of the representation of the human form on the Rorschach is an ideal data base for assessing an individual's representational world—his conception of people, including himself, and their actual and potential interactions. The representation of people, that is, object representations, have both structure and content" (Blatt & Lerner, 1983, p. 8). The structural aspects of object representations are emphasized in the Rorschach scoring system developed by Blatt, Brenneis, Schimek, and Glick (1976) that provides a developmental analysis of object representations in terms of such categories as differentiation, articulation, and integration of object and action. The content and affective themes of object representations are emphasized in the Rorschach scoring system developed by Mayman (1967) that emphasizes phenomenological dimensions such as affect states, ego states, experience of self, and sense of identity.

An object relations scoring system for the TAT has also been developed by Westen (1991) in which stories are rated for complexity of representations of people, affective tone of relationship paradigms, capacity for emotional investment, and understanding of social causality. A similar scoring system has been developed for the Picture Arrangement subtest of the WAIS (Westen, 1991, p. 72). In conclusion, the three major instruments of the original Menninger battery continue to show promise under a revised conceptual orientation that is most compatible with current thinking in personality, social, clinical, and developmental psychology.

4.12.3 PERSONOLOGICAL TRADITION

4.12.3.1 Historical Background

The "storied" nature of human conduct (Sarbin, 1986) has been recognized for many centuries within the disciplines of history, literature, and most of the social sciences. Within the much more recent personological tradition in personality assessment, the person is taken to be the basic unit of observation and the person's life story is considered to be the preferred way in which the person is to be understood (McAdams, 1994). The origins of the personological tradition, and in fact the origins of academic personality psychology itself, can be traced most directly to Harvard University in the 1930s. At that institution, Gordon Allport (1937) wrote the first textbook on personality, which defined the person as the basic unit of observation. Subsequently, he emphasized the use of personal documents in psychobiography (Allport, 1942, 1965) and spent a lifetime pondering the question of "How shall a psychological life history be written?" (Allport, 1967). At the Harvard Psychological Clinic, Murray (1938) introduced a multiform organismic method for studying "lives in progress" (White, 1952), in which an interdisciplinary team of investigators applied a variety of assessment procedures to the study of individuals over the course of their lives. During World War II, a variant of this procedure was employed in the selection of intelligence agents and saboteurs (Office of Strategic Services, 1948), and subsequently this approach spawned a variety of successful peacetime assessment programs (e.g., MacKinnon, 1975; Stern, Stein, & Bloom, 1956).

Murray's enduring contributions to the personological paradigm go well beyond those just mentioned. During his 60 years at Harvard, Murray was a source of personal inspiration for an extraordinarily talented and diverse group of students, colleagues, and visitors who, over the years, have applied and expanded his "personology" up until the present time. Early associates at the clinic included Samuel Beck, Erik Erikson, Jerome Frank, Daniel Levenson, Donald MacKinnon, Silvan Tomkins, and Robert White. Dan McAdams and William McKinley Runyan are more recent products of this Harvard tradition.

4.12.3.2 Conceptual Framework

Murray's (1938) personology provided a set of orienting attitudes that guided the multiform (many assessors, many tests), organismic (holistic) approach to the study of lives over time (e.g., White, 1966, 1975). Murray's (1959) conceptual framework was meant to serve as "the scaffold of a comprehensive system," rather than as a completed formal theory. Nevertheless, Murray (1938) introduced a number of concepts that have subsequently proven useful in guiding the study of lives. By taking the life cycle of the individual as the largest unit of study, Murray was committed to studying personality "the long way" (White, 1981), and he introduced units of time varying in duration and complexity from the proceeding (single episode) to the unity-thema (central life motif). A thema may be understood in terms of the interaction of needs (for which Murray developed his famous taxonomy) and press (environmental facilitation or obstruction of a need). The TAT (Murray, 1943) was developed as a projective measure of need–press interaction and has been utilized in large-scale studies of needs for achievement (McClelland, 1961), power (Winter, 1973), and intimacy (McAdams, 1989).

Erik Erikson's (1950) psychodynamic theory of personality development provided a more explicit account of the stages of psychosocial development over the entire life span (from the original psychosocial crisis of "trust versus mistrust" to the final crisis of "ego-integrity versus despair"). His theory informed his own classic psychobiographies, such as those of

Martin Luther (Erikson, 1958) and Gandhi (Erikson, 1969), as well as contributing to more recent psychobiographical efforts (e.g., Stewart, Franz, & Layton, 1988). More recently, in a book entitled *The stories we live by: Personal myths and the making of the self*, McAdams (1993) presented a neo-Eriksonian theory of identity development that is enriched by more contemporary concepts such as image, prototype, and script, and that is guided by the metatheoretical concepts of agency and communion (Bakan, 1966). This work has been hailed as "the most original and important new book on personality theory since George Kelly's *Psychology of personal constructs*" (Hogan, 1994, p. 356). The heuristic potential of McAdams' conceptual framework is suggested by the quality and quantity of critical response it has elicited from personality psychologists representing diverse theoretical perspectives (see McAdams, 1996 and peer commentary therein). Although McAdams' framework is more formal, explicit, and testable than earlier efforts, its roots in the formulations of Allport and Murray are easily traceable (McAdams, 1994).

4.12.3.3 Assessment Instruments

In what is now widely recognized as the definitive general treatise on life histories and psychobiography, Runyan (1982) observed:

> It should be clear that there is no single life history method, any more than there is a single personality research method, and that life histories may be studied through phenomenological self-reports, archival research, prospective longitudinal research, and experimental research. (p. 6)

Personality assessment psychologists from Murray to McAdams have recognized the need for methodological pluralism (Craik, 1986) in the study of lives, and for that reason the "boundaries" of the personological paradigm have historically been somewhat more permeable than those of the other paradigms considered in this chapter. Nevertheless, it would be inaccurate to characterize this paradigm as "eclectic," because the diversity of methods employed reflects the different levels of analysis encompassed by the term "life history," rather than the selective use of theories and methods to "explain" a given life. Following Kluckhohn and Murray (1953), Runyan (1982) distinguished three levels of generality in the social sciences: the universal (general laws of human behavior); the group (differences in sex, social class, culture); and the individual (distinctive, distinguishing characteristics of a particular person) and surveyed attempts to establish acceptable criteria for interpretations at each level. Although personologists in general, and clinicians in particular, are primarily concerned with the individual, an awareness of the larger enterprise that Runyan portrays serves to clarify the nature and goals of individual personality assessment. And for those few who might seriously be considering becoming psychobiographers, Alan Elms' (1994) book is essential reading.

The 25 different assessment procedures employed for the study of individuals at the Harvard Clinic (Murray, 1938) were indeed "multiform" in terms of both methods and the assessors who employed them; for example, autobiography (Murray), hypnosis (White), level of aspiration (Frank), dramatic productions (Erikson), and Rorschach (Beck). Perhaps of greatest interest to the contemporary clinician is the case study method in which some form of interview is employed with all the attendant advantages and limitations of retrospective, introspective, and qualitative methods (see Runyan, 1982, chap. 8). The procedures employed by McAdams (1993, chap. 10) provide an excellent example of a theory-driven approach to the interview.

4.12.3.4 Interpretive Principles

The variety of personality research methods for studying an individual's life history is reflected in a similar variety of interpretive principles associated with different methods. In this context, the interpretive principles elucidated by Alexander (1990) would appear to be "mainstream" in the sense that they evolved directly from the framework of Murray and his co-workers (especially Tomkins 1947, 1979) at the Harvard Psychological Clinic.

In analyzing data from directed interviews or autobiographical essays, Alexander (1990) looks for recurring dynamic sequences (scripts, themas, guiding messages) that may be revealed by "letting the data speak" or by "asking the data a question." In the former method, the typically large data set may be reduced by identifying "significant" material according to the following nine criteria of salience: (i) primacy (that which occurs first), (ii) frequency (that which occurs often), (iii) uniqueness (that which is unusual or odd), (iv) negation (that which is denied or disavowed), (v) emphasis (that which is either overemphasized or underemphasized), (vi) omission (that which is missing by normative standards or by implication), (vii) error or distortion (factual errors and Freudian slips), (viii) isolation (that which does not "fit" and non sequiturs), and (ix) incompletion (that which is not finished or lacks closure).

The method of "asking the data a question" is similar to that employed in the analysis of TAT protocols for predetermined categories such as "power motivation" (Winter, 1973). The database of interview material is reduced by selecting every sequence or incident related to the questions posed by the investigator. When applied to interview material, this method retains the "projective" advantage of addressing issues that the storyteller did not consciously intend to describe or deal with, while circumventing problems such as the identification of the "hero" of the narrative (Alexander, 1990).

4.12.3.5 Applications and Current Status

In recent years, there appears to have been a "back to basics" movement in personality assessment research (Wiggins & Pincus, 1992) that has rekindled interest in the fundamental assumptions of several paradigms, including the personological: "Once, again, it is okay to study the 'whole person.' Better, contemporary personologists insist, as did pioneers like Gordon Allport, that such an endeavor is the personologist's *raison d'être*" (McAdams, 1988, p. 1).

In terms of clinical applications, it should be borne in mind that the personological tradition has tended to focus on relatively normal, nonclinical samples and that within this tradition, life histories have been viewed as relatively veridical accounts of what has happened in a person's life (Runyan, 1982) or as imaginative reconstructions of the past (McAdams, 1993). It is also important to recognize that personality assessment within the personological paradigm occurs on a different level than traditional psychodiagnostic assessment (Alexander, 1990). Whereas personological assessment attempts to understand current personality functioning in terms of an individual's own life history, traditional psychodiagnostic assessment is concerned with determining the individual's membership in a group or class of individuals that differs from other groups in terms of psychopathology.

> A major difference between the two approaches is that the results of the former [personological] can easily be directed toward answering the questions intended by the latter [psychodiagnostic]. The reverse is, unfortunately, a low probability event in anything other than a global sense. To designate someone as obsessive or hysteric, or depressive, or schizophrenic will place the focus on particular salient aspects of functioning but say little about the dynamics in that individual leading to that particular form of functioning. (Alexander, 1990, p. 7)

4.12.4 MULTIVARIATE TRADITION

4.12.4.1 Historical Background

Sir Francis Galton's (1888) method for analyzing the "co-relations" between twin pairs was refined by Pearson (1896) and utilized effectively by Spearman (1904) in identifying a "general factor" of intelligence (*g*) that appeared to "underlie" various tests of mental abilities. Factors are statistical abstractions that summarize the relations among test scores in terms of underlying or "latent" variables which may be thought of as operating at several levels. For example, the intelligence quotient (IQ) could be considered to be a general higher-order factor that summarizes relations between verbal and performance major group factors, which in turn, summarize relations among multiple minor group factors (Vernon, 1950).

Raymond B. Cattell, the founding father of the multivariate tradition of personality assessment, was a student of Spearman and was among the first to apply factor-analytic methodology to the study of temperament (e.g., Cattell, 1933). Using cluster-analytic procedures, Cattell (1943) reduced Allport and Odbert's (1936) exhaustive compilation of trait-descriptive terms from Webster's unabridged dictionary to 35 "surface traits" (see John, 1990). He administered the 35 surface-trait variables (e.g., talkative vs. silent) to respondents in a series of peer-rating studies and eventually concluded that no less than 16 "source traits" could account for the interrelations among the 35 surface clusters (Cattell, 1949).

The Guilfords (1936, 1939) were also pioneers in the application of factor analysis to personality data, and they assembled evidence for the four interpretable factors of "shyness," "rhathymia," "depression," and "liking for thinking" which would now be called " extraversion," "conscientiousness," "neuroticism," and "intellect," and which (together with "agreeableness") constitute the currently important five-factor model (FFM) of personality (Digman, 1996). A decade later, Eysenck (1947) factored the intercorrelations among presenting symptoms of psychiatric patients and found two factors (extraversion and neuroticism) that had both theoretical (Jung, 1971) and empirical (MacKinnon, 1944) precedents (see Eysenck, 1990, pp. 95–98). By the 1950s, the systems of Eysenck (1953), Cattell (1957), and Guilford (1959) had become extensive alternative theories of personality structure.

The history of the multivariate tradition is a curious one that has recently been reconstructed by Digman (1996). Briefly, Digman argues that as early as the 1930s, there was evidence for the generality and replicability of a FFM of personality that consisted of surgency/extraversion (E), agreeableness (A), conscientiousness (C), neuroticism (N), and intellect/openness (O). Over a period of almost 50 years, a series of cumulative studies may be traced (e.g., Fiske, 1949; Norman, 1963; Tupes & Christal, 1961) that led to an emerging consensus on the utility and generalizability of this five-factor representation (e.g., Digman, 1979; Goldberg, 1977; Wiggins, 1973b). By the 1980s, there were three distinctive interpretations of the nature of these five factors (Costa & McCrae, 1985; Goldberg, 1981; Hogan, 1986), that were followed in the 1990s by still more interpretive perspectives (e.g., Buss, 1996; Wiggins & Trapnell, 1996). It should be noted, however, that although there are a number of workers within the multivariate paradigm who agree on the number, if not the nature, of the factors in the FFM, there are many who strongly contest both the number of factors and their significance (e.g., Block, 1995; Eysenck, 1992; Hough, 1992; Waller & Ben-Porath, 1987).

4.12.4.2 Conceptual Framework

Cattell's (1957) master plan for constructing a theory of personality presupposed a rigorous and representative sampling of the language personality sphere that, in effect, defined the universe of content of behaviors to be explained (Wiggins, 1984). To make certain that this universe of content was properly defined, Norman (1967) replicated the earlier lexical research of Allport and Odbert (1936), using a more recent unabridged dictionary, and subsequently employing more rigorous clustering procedures than those used by Cattell (see John, 1990). Norman's taxonomy of personality attributes was subsequently employed by Goldberg (1981, 1990, 1993) in a program of methodologically elegant research on the natural language of personality that firmly established what he termed the "Big Five" dimensions identified by earlier investigators.

Goldberg's taxonomic research program revitalized interest in the five-factor model and within a relatively brief period of time a variety of new instruments were developed (e.g., Botwin & Buss, 1989; Costa & McCrae, 1985; Goldberg, 1992; Hogan, 1986; Trapnell & Wiggins, 1990) that measured these five dimensions within an equal variety of conceptual frameworks, for example, evolutionary theory (Buss, 1996), trait theory (McCrae & Costa, 1996), lexical theory (Saucier & Goldberg, 1996), socioanalytic theory (Hogan, 1996), and interpersonal theory (Wiggins & Trapnell, 1996). Moreover, a series of investigations by Costa and McCrae revealed that instruments employed in the other four traditions of personality assessment—psychodynamic (Myers & McCaulley, 1985), personological (Jackson, 1984), empirical (Hathaway & McKinley, 1983), and interpersonal (Wiggins, Trapnell, & Phillips, 1988)—showed meaningful convergences with some or all of the dimensions of the FFM (Wiggins & Trapnell, 1997).

4.12.4.3 Assessment Instruments

The NEO Personality Inventory (NEO PI-R; Costa & McCrae, 1992b) is the instrument of choice for measuring the dimensions of the FFM of personality. This test provides global measures (domain scores) for each of the five factors and six more specific measures (facet scores) within each of the five domains: (i) neuroticism (anxiety, angry hostility, depression, self-consciousness, impulsiveness, vulnerability); (ii) extraversion (warmth, gregariousness, assertiveness, activity, excitement-seeking, positive emotions); (iii) openness (fantasy, aesthetics, feelings, actions, ideas, values); (iv) agreeableness (trust, straightforwardness, altruism, compliance, modesty, tender-mindedness); and (v) conscientiousness (competence, order, dutifulness, achievement striving, self-discipline). The "astonishingly fruitful research collaboration" (Block, 1995) of Costa and McCrae has produced scores of publications that document the substantive, structural, and empirical validity of this instrument.

4.12.4.4 Interpretive Principles

There are notable differences in interpretive principles suggested by proponents of different multivariate instruments and these would appear to reflect different claims as to the extensiveness and importance of the "universe of content" measured by each instrument, and the theoretical basis on which that content is interpreted for each instrument. With respect to the former, the differences among alternative theories of personality structure within the multivariate tradition have often reflected preferences for different methods of factoring correlations among the phenotypic variables of personality study. Thus, Cattell, who argued for 16 primary source traits, as well as the originator of the multiple-factor method himself (Thurstone, 1934), have both been accused of "overfactoring" (Digman, 1996); while Eysenck (1992), who disputes anything beyond three factors, has been accused of "underfactoring" (Costa & McCrae, 1992a). That almost half a century of essentially methodological disagreements may be approaching resolution can be seen in the emerging consensus that the FFM of personality is an appropriate "working model" of the universe of content of personality structure that may (and should) be expanded, as necessary, whenever the incremental validity of additional dimensions are demonstrated (Wiggins, 1996).

The theoretical bases on which a five-factor profile may be interpreted are of greater interest to the practitioner. And, as is true of a number of instruments that originated in other personality assessment traditions, it is possible to interpret the FFM from a variety of theoretical perspectives. The NEO PI-R (Costa & McCrae, 1992b) provides explicit principles for interpreting normal and abnormal behavior from the standpoint of modern trait theory (McCrae & Costa, 1996). The Hogan Personality Inventory (Hogan & Hogan, 1992) provides explicit interpretive principles for personnel selection in the workplace from the standpoint of socioanalytic theory (Hogan, 1996). A new edition of the venerable Sixteen Personality Factor Questionnaire (Cattell, Cattell, & Cattell, 1993) provides interpretive principles for five "global factor scales" (Cattell, 1994) from the standpoint of a long-standing "mainstream" personality theory (Wiggins, 1984); and the possibilities for interpreting other well-established instruments, such as the Personality Research Form (Jackson, 1984), from an FFM perspective, are under active investigation (e.g., Jackson, Paunonen, Fraboni, & Goffin, 1996).

4.12.4.5 Applications and Current Status

Historically, there has been little consensus regarding the relation between the normal dimensions of personality, measured by inventories developed within the multivariate tradition, and the dimensions and/or categories of psychopathology. Recently, however, there has been an increased conceptual and empirical focus on this issue, stimulated in part by the definition of personality disorders in terms of personality traits by the American Psychiatric Association (APA; 1980) and by the availability of new instruments and techniques for addressing this problem (Strack & Lorr, 1994).

It would appear that the global dispositions measured by the NEO PI-R provide a comprehensive assessment of emotional (N), interpersonal (E & A), motivational (C), and cognitive (O) styles that are not measured by traditional clinical instruments. As Costa (1991b) noted, "This portrait can be used in psychotherapy: to formulate a tentative diagnosis; to aid the clinician's development of empathy; to help select appropriate treatments; to identify the client's strengths; and to anticipate the outcome, duration, and course of therapy" (p. 395). A detailed and perceptive account of how this might be done has been provided by Miller (1991). The notable longitudinal stability of NEO PI-R dimensions in the adult personality (McCrae & Costa, 1990) has led to a revised view of the therapeutic enterprise:

> we expect that clients will bring these dispositions with them to psychotherapy, and that the therapist should (a) take them into account when trying to understand the individual and his or her problems, and (b) tailor the therapy to fit the needs and styles of the client. (McCrae, 1991, p. 406)

The most extensive psychodiagnostic application of the FFM in general, and of the NEO PI-R in particular, has been to the diagnosis and understanding of personality disorders (Costa & Widiger, 1994). The definition of these disorders in terms of dysfunctional personality traits, by a committee of the APA (1980), stimulated an unprecedented collaborative effort among psychiatrists, psychologists, and psychometricians to find common grounds for characterizing these disorders. It was found, for example, that both the APA diagnostic criteria and the clinical literature on personality disorders were compatible with descriptions of each disorder generated from the facet and domain scales of the NEO PI-R (see Widiger, Trull, Clarkin, Sanderson, & Costa, 1994, Table 1, p. 42).

Subsequent advances in relating the FFM to the personality disorders are too numerous to summarize, but may be found in current journals, particularly the *Journal of Personality Disorders*. The current literature may be viewed as reflecting yet another milestone in the long-standing relation between the FFM and the multivariate paradigm, which Digman (1994) characterized as follows:

> Now, after many years of lying on the closet shelf of personality theory, the model has been dusted off, "as good as new," and appears to be for many researchers ... a very meaningful theoretical structure for organizing the myriad specifics implied by the term *personality*. (p. 13)

4.12.5 EMPIRICAL TRADITION

4.12.5.1 Historical Background

The MMPI (Hathaway & McKinley, 1943) is, and has been for many years, the most widely used inventory of personality and psychopathology. To understand the 50-year history of this instrument is to understand the history of objective personality assessment for the same time period. As Craik (1986) put it, in his historical survey of personality research methods, "the MMPI came to serve as the centerpiece of this period's [post-WWII] predominant or mainstream agenda" (p. 21). Within that agenda, one can discern the operation of two separate dialectical processes over time: ongoing disputes between the developers of the MMPI and their critics and bipolar shifts in conceptualization that have occurred within the evolving conceptual and interpretive frameworks of the developers of the MMPI. The ongoing disputes reflect the fact that, because of its prominence, the MMPI came to be associated with such contentious issues as clinical versus statistical prediction (Meehl, 1954) and response styles (Wiggins, 1962). The shifts in conceptualization reflect the virtuosity and intellectual flexibility of the developers of the MMPI who were able to shift from typological categories to continuous trait dimensions; from discriminant validity of differential diagnoses to the construct validity of scales and profiles; and from denigration of self-reports to the canonization of item content (Ben-Porath, 1994).

The dialectical processes just described were enacted by a remarkably diverse group of scientists/practitioners whose program of clinical research had its roots in the unique combination of behavioral, biological and psychometric thinking that prevailed at the University of Minnesota in the 1930s and 1940s (Meehl, 1989). Stark R. Hathaway was an originator of the MMPI, a mentor for successive generations of Minnesota students and a merciless critic of his own instrument (e.g., Hathaway, 1972). Paul E. Meehl—learning theorist, philosopher of science, psychoanalyst, and taxonometrician—is a legend in his own time, the principal theorist of the MMPI, and arguably the major figure in the field of personality assessment since the late 1950s. W. Grant Dahlstrom is the Talmudic scholar of the MMPI, whose meticulous organizations of that vast literature have informed and influenced generations of clinicians and researchers (e.g., Dahlstrom & Dahlstrom, 1980; Dahlstrom, Welsh, & Dahlstrom, 1972–1975; Welsh & Dahlstrom, 1956). James N. Butcher is a distinguished editor, scholar, and researcher who is principal author of the revised MMPI (MMPI-2; Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), the new MMPI content scales (Butcher, Graham, Williams, & Ben-Porath, 1990), the adolescent version of the MMPI (MMPI-A; Butcher et al., 1992), and the MMPI automated clinical report (Butcher, 1993).

4.12.5.2 Conceptual Framework

The rationales underlying four distinguishable strategies of objective (as opposed to projective) test construction are based on differing views regarding the meaning of subjects' responses to objective test items (Wiggins, 1973b)

(i) *The rational (correspondence) strategy*. This assumes a one-to-one correspondence between a subject's "report" ("I am anxious") and a palpable internal state of the subject (the experience of anxiety) (Buchwald, 1961). This assumption was the cornerstone of introspectionism in early experimental psychology and it was the principal rationale underlying the earliest personality inventories (e.g., Woodworth, 1917).

(ii) *The empirical (instrumental) strategy*. This views a subject's "utterance" as "an intrinsically interesting and significant bit of verbal behavior, *the nontest correlates of which must be discovered by empirical means*" (Meehl, 1945, p. 297, emphasis added). If it were established empirically that a false response to the item "I am anxious" was more characteristic of hospitalized hysterics than of a normal control group, that particular bit of verbal behavior would become meaningful, and would illustrate the instrumental value of verbal behavior as a tool in psychodiagnostics. This philosophy was evident in the early behavioristic critique of introspectionism in experimental psychology and in later critiques of existing rational personality inventories of the 1930s (Humm & Wadsworth, 1935; Landis & Katz, 1934; Landis, Zubin, & Katz, 1935). The earliest example of a major inventory constructed under an empirical strategy was the Vocational Interest Blank (Strong, 1927), which served as the prototype for the construction of the MMPI.

(iii) *The constructive (substantive) strategy*. This views a subject's response as a manifestation of an underlying personality construct that is embedded in an interlocking system of laws that relate constructs to one another and to observable properties of the environment (Cronbach & Meehl, 1955). The meaning of a construct is given by the empirical laws into which it enters and the significance of a construct is given by the number of such lawful relations discovered. The construct validity of a personality scale is estimated from "the proportion of test score variance that is attributable to the construct variable" (p. 289).

(iv) *The interpersonal (self-presentational) strategy*. This views a subject's response as an interpersonal communication between the subject and the tester (or the institution that the tester represents) (Carson, 1969b; Leary, 1957). The meaningfulness of such a communication is dependent upon both the subject's and the tester's views of the meaning of test responses in a particular testing situation (e.g., hospital admission, vocational guidance). Thus, the subject may mean to communicate a complaint ("I am anxious") and the tester (or the scoring system employed by the institution) may encode this as "neuroticism." The subject may view the testing situation as an opportunity for self-disclosure (Jourard, 1964) and the examiner may view it as an opportunity for impression management (Goffman, 1959). Elsewhere it has been argued that the interpersonal view of test responses has much to commend it, not the least of which is the likelihood that this is the frame of reference which subjects themselves adopt (Wiggins, 1966).

4.12.5.3 Assessment Instruments

Construction of the MMPI began with the generation of a large pool of items that were considered representative of "behaviors of significance to the psychiatrist" (Hathaway & McKinley, 1940). These items were presented in true–false format to several groups of diagnosed psychiatric inpatients (e.g., depressives) and to a large group of normal control subjects. The proportion of patients in a given diagnostic group who responded "true" ("endorsement") to each item (e.g., 80%) was compared with the proportion of normal subjects who had responded "true" to that item (e.g., 10%), in order to identify discriminating items that might be keyed (in this instance, "true") on a clinical scale (e.g., depression scale; Hathaway & McKinley, 1942). Innovative procedures were then applied in the development of three validity scales that served to identify sources of invalidity or "faking" in test responding: a "lie scale" (*L*) with items of high desirability and low endorsement, an "infrequency scale" (*F*) with items of low desirability and low endorsement, and a subtle "correction scale" (*K*) that measures defensiveness when high and self-criticalness when low. The resultant three validity scales, eight clinical scales (hypochondriasis, depression, hysteria, psychopathic deviate, paranoia, psychasthenia, schizophrenia, hypomania), a masculinity/femininity scale, and a social introversion scale constitute the MMPI profile that was normed and standardized on the original sample of normal control subjects.

4.12.5.4 Interpretive Principles

4.12.5.4.1 Empirical strategy

The original purpose of the MMPI was to aid psychiatrists in their assignment of patients to the traditional psychiatric diagnostic categories of that time. The conservative rationale of the empirical strategy permitted such statements as "This subject's pattern of verbal behavior resembles more closely that of a group of hospitalized schizophrenics than it does that of a normal control group." This fact, together with evidence from other sources, was suggestive of the working diagnosis of "schizophrenia." Unfortunately, the individual clinical scales were not successful in subsequent attempts to discriminate diagnostic groups from normals (Hathaway, 1960), due most likely to lack of power in the original statistical comparisons and to unreliability of both predictor and criterion measures.

4.12.5.4.2 Constructive strategy

Ben-Porath (1994) provides an excellent historical summary of the "reinvention of the MMPI" following the failure of the empirical strategy and of its subsequent "evolution into an omnibus measure of personality" within a construct-oriented perspective. The highlights of this shift over a 50-year period of unprecedented research and clinical work include emphases upon: (i) MMPI profile configurations, rather than on single scales (e.g., Gough 1946); (ii) normal personality correlates of profile types (e.g., Black, 1956); (iii) additional empirically and substantively derived scales that broadened the nomological network of MMPI investigation (e.g., Morey, Waugh, & Blashfield, 1985), and (iv) actuarial prediction systems based on configural profile types (e.g., Marks & Seeman, 1963).

4.12.5.4.3 Interpersonal strategy

Loevinger's (1957) formulation of the substantive component of construct validity provided an even greater contrast to the original empirical perspective of the MMPI. Nevertheless, workers within the MMPI tradition for the most part continued to pursue the other components of construct validity just described. Interest in the "content" of patients' communication of complaints via the MMPI remained minimal until the appearance of Wiggins' (1966) MMPI Content Scales. In terms of Loevinger's distinctions, these content scales appeared to provide: (i) representative coverage of the universe of content of the MMPI item pool (see Johnson, Butcher, Null, & Johnson, 1984), (ii) psychometrically sound measures of 13 dimensions of self-report that were interpretable with reference to previous studies of the factorial structure of the MMPI (Welsh, 1956), and (iii) empirical evidence of convergent and discriminant validity with reference to psychiatric diagnostic categories (Wiggins, 1966; Payne & Wiggins, 1972). Perhaps of greater interest to the MMPI community was the potential usefulness of these content scales in individual psychodiagnostic appraisal (e.g., Nichols, 1987). Variants of the original content scales are now an official supplement to the clinical scales of MMPI-2 (Butcher et al., 1990) and their incremental contribution to the differential diagnosis of psychopathology appears highly promising (e.g., Ben-Porath, Butcher, & Graham, 1991).

4.12.5.5 Applications and Current Status

The MMPI developed in the 1940s was, by contemporary standards, based on inadequate and outdated norms, replete with offensive and anachronistic items, and patently unsuited to the diagnostic task for which it was devised. The clinical scales were derived by less than optimal contrasted group procedures (Jackson, 1971) that, from the beginning, appeared unreplicable (Benton, 1949). In the absence of a coherent theoretical rationale, the profiles, code-types, and actuarial systems based on these scales have an ambiguous conceptual status (Helmes & Reddon, 1993). Pressures to restandardize, revise, or replace this relic have existed almost from its inception, culminating in a historically important summit meeting (Butcher, 1972) in which the third option was seriously considered (Wiggis, 1973a). Once again, however, the resilient and perdurable Minneapolis Group (Butcher et al., 1989) rose to the challenges from within and without to produce what was optimistically dubbed "MMPI-2" (leaving open the possibility of MMPI-3 in the year 2035).

Although the original MMPI is a disgruntled psychometric critic's dream come true, it is difficult to ignore the past and present status of the MMPI as our most widely used objective personality test. Given what appeared to be the lesser of two evils, the personnel of the MMPI Restandardization Project opted to emphasize continuity with the vast interpretive and empirical database accumulated for the original clinical and validity scales while simultaneously removing inappropriate items, correcting psychometric deficiencies where possible, and generating new content scales. Shorn of its dated and politically incorrect items, the lamb-like content of the MMPI-2 is now clothed in the lupine garments of computer technology and state-of-the-art methodology (e.g., uniform *T*-scores, adaptive testing, measurement of variable response inconsistency). MMPI-2 appears to be replacing the original in most clinical settings (e.g., Webb, Levitt, & Rojdev, 1993), although there continue to be criticisms from both without and within the MMPI community (e.g., Caldwell, 1997).

In 1972, Hathaway concluded: "So, in summary, we are stuck, I think, with the MMPI ... for a dreary while longer, although a prophet may even now be wandering in the psychometric wilderness" (1972 p. 40). There is little doubt that we will be "stuck" with MMPI-2 for many years to come, although the paths of the prophets are now more discernible (e.g., Costa, 1991a; Morey, 1991).

4.12.6 INTERPERSONAL PARADIGM

4.12.6.1 Historical Background

The interpersonal circumplex model had its origins in the writings of Harry Stack Sullivan (1953) who introduced a number of original and radical ideas into the American psychiatry of the 1940s. Although not entirely liberated from Freud's spatial-hydraulic metapsychology, Sullivan was "behavioral" in the sense that his primary emphasis was upon the things that persons do to one another in interpersonal transactions, rather than upon internal processes that persons might "have." His oft-cited definition of personality as "the relatively enduring pattern of recurrent interpersonal situations which characterize a human life" represents an even greater departure from psychoanalytic thought, as well as a unique perspective within personality theory itself.

Sullivan was influenced by Lewin's (1938) field-theoretical conceptualization of contemporaneous, bidirectional influences in "psychological fields," which led him to define the interpersonal situation as the basic unit of observation in psychiatry. This idea does not connote a separate "person" or "persons" who may be considered independently from the complex field (situation) of bidirectional causalities in which they are embedded; nor does it hold out the hope of capturing such complexities as "interaction" terms in analyses of variance.

The Kaiser Foundation Research Project, in which Timothy Leary (1957) was the most preeminent investigator, attempted to operationalize Sullivanian concepts in terms of concrete measurement procedures. An ordinary language analysis of clinicians' observations of the things that patients did to each other (and to themselves) in group psychotherapy led to a taxonomy of interpersonal behaviors that appeared to be empirically well-captured by a circular arrangement of interpersonal variables organized around the coordinates of "dominance" and "affiliation." LaForge, Leary, Naboisek, Coffey, and Freedman (1954) derived the basic trigonometry of what would later be called a "circumplex," without knowledge of Guttman's (1954) related work on that topic.

Notable contributions during the 1960s included the conceptualization of both maternal and child behavior within an interpersonal circumplex framework (Schaefer, 1961), a psychometrically sophisticated replication of the circumplex within a clinical population (Lorr & McNair, 1963), and a highly influential integration of the circumplex with the clinical, social, and experimental psychology of that time (Carson, 1969a). Alternative conceptual formulations of the interpersonal model were presented in the 1970s (e.g., Benjamin, 1974; Kiesler, 1979; Wiggins, 1979), and during the 1980s the model was applied to psychotherapy (Anchin & Kiesler, 1982), complementarity (Kiesler, 1983), and interpersonal problems (Horowitz, Rosenberg, Baer, Ureno, & Villasenor, 1988). Among the contributions of the 1990s have been an updated and psychometrically-sound version of the original interpersonal checklist (Wiggins, 1995), a comprehensive exposition of contemporary interpersonal theory and research (Kiesler, 1996), and a presentation of the impressive variety of contexts in which the interpersonal circumplex model has been applied (Plutchik & Conte, 1997).

4.12.6.2 Conceptual Framework

The radical interpersonalism of Sullivan (1953) may be difficult to comprehend on first exposure because of our ingrained "individualist language" (p. 50) for describing personality as reflecting attributes of a discrete individual who is "separate" from others and from a shared social environment. Theorists within the interpersonal paradigm have attempted to operationalize Sullivan's conceptualization of personality in ways that avoid this individualistic bias, by defining personality as "nothing more (or less) than the patterned regularities that may be observed in an individual's relations with other persons, who may be real in the sense of actually being present, real but absent and hence 'personified' or 'illusory'" (Carson, 1969a, p. 26).

On a metatheoretical level, it is helpful to think of the dominance and affiliation axes of the interpersonal circumplex in terms of Bakan's (1966) concepts of "agency" (mastery, self-assertion, self-expansion) and "communion" (union with a larger social or spiritual entity), respectively (Wiggins, 1991). These concepts are compatible with Sullivan's emphasis on the communal context of interpersonal transactions and with his belief in the importance of the social sciences for understanding interpersonal situations. When conjoined with Foa and Foa's (1974) theory of the exchange of love (communion) and status (agency) in interpersonal transactions, these concepts provide a rich conceptual framework for the measurement and understanding of interpersonal behavior (Wiggins & Trapnell, 1996).

4.12.6.3 Assessment Instruments

4.12.6.3.1 Interpersonal Adjective Scales

The Interpersonal Ajective Scales (IAS; Wiggins, 1995) evolved from a psychological taxonomy of trait-descriptive terms that was developed within the framework of a larger program of collaborative research on language and personality (Goldberg, 1977). Within a representative pool of trait-descriptive adjectives selected from an unabridged dictionary, an "interpersonal domain" was distinguished from other domains, such as characterological, temperamental, and cognitive domains (Wiggins, 1979). Approximately 800 interpersonal adjectives were assigned to the original categories of the interpersonal circumplex (Leary, 1957) on both conceptual and empirical grounds. Using computer-based multivariate procedures it was found that scales based on the original categories failed to meet certain circumplex criteria that could be better met with scales based on the revised categories that now constitute the IAS (Wiggins, 1995). The IAS consists of 64 adjectives that respondents rate for self-descriptive accuracy on an eight-place Likert scale ranging from "extremely inaccurate" to "extremely accurate." Eight scales, or "octants," of eight items each, assess the interpersonal dispositions listed in the first column of Table 1. The PA octant, for example, includes items such as "dominant," "forceful," and "assertive."

4.12.6.3.2 Inventory of Interpersonal Problems

Horowitz (1979) transcribed statements of interpersonal problems expressed by psychiatric outpatients in the course of videotaped intake interviews and employed these statements as items in the construction of the Inventory of Interpersonal Problems (IIP), in which respondents are required to indicate the extent to which each of 127 statements is problematic on a five-place Likert scale ranging from "not at

Table 1 Octant scales from three interpersonal assessment instruments.

	IAS Interpersonal Adjective Scales	*IAS Inventory of Interpersonal Problems*	*IAS Impact Message Inventory*
PA	Assured–dominant	Domineering	Dominant
BC	Arrogant–calculating	Vindictive	Hostile–dominant
DE	Cold-hearted	Cold	Hostile
FG	Aloof-introverted	Socially avoidant	Hostile–submissive
HI	Unassured–submissive	Nonassertive	Submissive
JK	Unassuming–ingenuous	Exploitable	Friendly–submissive
LM	Warm–agreeable	Overly nurturant	Friendly
NO	Gregarious–extraverted	Intrusive	Friendly–dominant

all" to "extremely" (Horowitz et al., 1988). Subsequently, Alden, Wiggins and Pincus (1990) developed a circumplex version of this inventory (IIP-C) that consists of eight scales, of eight items each, that assess the interpersonal problems listed in the second column of Table 1. The PA octant, for example, includes items such as "I try to control other people too much."

4.12.6.3.3 Impact Message Inventory

The Impact Message Inventory (IMI) is a highly original and promising method of assessment that is based on Kiesler's (1988) theory of interpersonal communication in psychotherapy. The theory postulates that disordered individuals are unaware of the unintended, inappropriate, and ambiguous messages they repetitively "send" to others and that they are therefore confused and distressed by the pattern of negative responses they consistently evoke or "pull" from others. The IMI attempts to identify the location within the interpersonal circumplex of these patterns of negative response evoked in others, as a means of gaining insight into a client's maladaptive transactional behavior.

Items were generated from a content analysis of free responses to 15 interpersonal vignettes that described characters enacting 15 different interpersonal styles, similar to those found in the first column of Table 1. Respondents were asked to imagine themselves in the company of each of these characters and to record their covert reactions using the stem, "He makes me feel..." Content analysis of responses suggested three categories of covert reaction: direct feelings, action tendencies, and perceived evoking messages. The Octant version of the IMI consists of six items for each of the target stimuli listed in the third column of Table 1. For each octant, there are two items for each of the three categories of covert reaction to the target stimulus. Thus, for example, the PA scale includes two items each for direct feelings (e.g., "bossed around"), action tendencies (e.g., "I want to tell him to give someone else a chance to make a decision"), and perceived evoking messages (e.g., "He thinks he's always in control of things"). Respondents (e.g., a psychotherapist) are asked to imagine themselves in the company of a particular person (e.g., a psychotherapy patient) and to indicate the extent to which they experience the covert reactions on a four-place scale. Covert reactions to a target person (e.g., feeling "bossed around") are thus revealing of the personality and the interpersonal impact of that target person (e.g., rigidly dominant, PA).

4.12.6.4 Interpretive Principles

One of the most valuable features of the circumplex model is the opportunity it provides for interpreting interpersonal variables with reference to the geometric principles of a circle (LaForge et al., 1954). The variables of traditional multiscale inventories are typically displayed as "factor lists" (Hogan, 1983) in which the ordering and interrelations among variables lack both conceptual and interpretive significance. In contrast, the trigonometric procedures that can be applied to the variables of an interpersonal circumplex permit descriptions and diagnostic inferences that cannot be generated from traditional scales (Wiggins, Phillips, & Trapnell, 1989).

Some general principles of circumplex interpretation may be illustrated with reference to Figure 1, which presents the IAS profile of a 44-year-old woman who was employed as a senior bank manager. At the bottom of the figure are *T*-scores on the octant variables, expressed with reference to an appropriate normative group. These scores have been plotted on shaded sectors of the circle and they are interpreted as representing eight vectors in two-dimensional space. The mean or average directionality of these eight vectors is of critical diagnostic significance because it determines the "typological" category to which this woman will be assigned. By trigonometric procedures, this average directionality was determined to be 90°, which falls exactly at the midpoint of the assured-dominant category (PA). Such an angular location is considered to be prototypical of individuals classified as pure "PA types." Had the location been at 110°, a more hostile manifestation of dominance (BC) would have been suggested; had it been at 65°, a more affiliative expression of dominance (NO) would have been suggested. But the protypicality of the present classification increases our confidence in asserting that the principal interpersonal style of this woman is one that emphasizes the exercise of power over others in a social context, by such activities as taking charge, making decisions, and winning arguments (Wiggins, 1995, p. 22).

The general shape of the profile in Figure 1 closely resembles the characteristic configuration of IAS profiles that is found in the average profiles of subjects in all IAS typological groups (Wiggins et al., 1989). The characteristic configuration of an IAS profiles is one in which the principal elevation occurs on the defining octant (in this case, PA), with secondary and approximately equal elevations occurring on adjacent octants (BC and NO), and diminishing and approximately equal elevations occurring on subsequent pairs of octants (DE and LM), (FG and JK), down to a highly truncated "opposite" (to the principal) octant (HI). Thus, across interpersonal situations, we would expect this woman frequently to behave in a forceful, assertive, dominant, and self-confident manner (PA); to somewhat less frequently behave in aggressive (BC) and gregarious (NO) ways; to seldom, if ever, behave in a submissive (HI) fashion, and so forth.

The vector length of an interpersonal profile is a measure of "deviance" in both a statistical and a psychiatric sense. In the former sense, vector length is the standard deviation of the eight interpersonal variables that indicates the "intensity" with which a pattern of interpersonal behavior is expressed. In the latter sense, high-variance profiles are associated with interpersonal "rigidity" and are found most often in psychiatric groups. The length of the arrow indicating angular location in Figure 1 is the vector length of the profile, which is approximately 1.8 standard deviations above that of the normative group. This would suggest that the pattern of interpersonal behaviors described above would be expressed vigorously, and quite possibly rigidly or intemperately.

Having established that this individual's profile is representative of those obtained by assured dominant "types," and that this pattern of behavior is expressed in a clearly differentiated fashion, interpretation would proceed with reference to the empirical literature of the interpersonal tradition that has examined both the dimension of assured-dominant (PA) and the characteristics of dominant "types" in both normal and psychiatric populations (Kiesler, 1996). This would include the literature of other instruments that have studied this location (PA) in contexts such as interpersonal problems (IIP-C), impact messages (IMI), and other contexts that have been studied by interpersonal researchers.

4.12.6.5 Applications and Current Status

The definition of the personality disorders in terms of personality traits by the APA (1980), and the availability of new instruments and techniques for assessing personality disorder, has resulted in an increased understanding of this diagnostic axis. For example, many of the *Diagnostic and statistical manual of mental disorders* (*DSM*) personality disorder categories have been shown to be well captured by the two-dimensional structures of the IAS (e.g., Wiggins & Pincus, 1989, 1994) and the IIP-C (e.g., Pincus & Wiggins, 1990; Soldz, Budman, Demby, & Merry, 1993). Similarly, clinicians' ratings of *DSM* personality disorder categories have been found to be well captured by an interpersonal circumplex model (e.g., Blashfield, Sprock, Pinkston, & Hodgin, 1985; Plutchik & Conte, 1986). And more recently, Benjamin (1995) has provided a detailed and perceptive description of procedures for the diagnosis of personality disorders within the framework of her variant of the interpersonal circumplex model.

The interpersonal tradition originated in the context of psychotherapy and, perhaps more than any other tradition, has contributed to an understanding of the therapeutic process itself (e.g., Anchin & Kiesler, 1982; Benjamin, 1995; Kiesler, 1988; Safran & Segal, 1990; Sullivan, 1953). The most notable contribution of this tradition to psychotherapy has been the circumplex structural model that provides a framework for representing dyadic interactions in the therapeutic relationship. A number of different assessment devices based on the interpersonal circumplex, and variants of that model (e.g., Benjamin, 1974), have proven useful in studies of psychotherapy process and outcome (Kiesler, 1996).

Gurtman (1996) has emphasized the construct validity of the circumplex version of Horowitz's Inventory of Interpersonal Problems (IIP-C; Alden et al., 1990) within the psychotherapy context. Henry (1996) has made

	PA	BC	DE	FG	HI	JK	LM	NO
T-Score	65	56	52	40	30	41	49	60

Angular location = 90°

Vector length T-score = 68°

Figure 1 IAS profile of a 44-year-old bank manager.

a similar case for the Structural Analysis of Social Behavior (Benjamin, 1974) as a common metric for programmatic psychotherapy research. Kiesler, Schmidt, and Wagner (1997) have stressed the conceptual advantages of the IMI in analyzing the psychotherapeutic relationship. And Kiesler (1996) has also emphasized the potential of the revised Check List of Psychotherapy Transactions (Kiesler, Goldston, & Schmidt, 1991) for measuring the interpersonal behavior of interactants in the therapy relationship. Taken together, the studies summarized in the aforementioned review articles constitute an impressive empirical literature that attests to the heuristic potential of the interpersonal circumplex model in psychotherapy research. The future of the interpersonal circumplex tradition for research in both psychodiagnostics and psychotherapy appears to be a bright one (Wiggins & Trobst, 1997).

4.12.7 CONCLUSION

In the introduction to this chapter, we considered the diagnostic work of a hypothetical clinician who was both well trained and well informed about personality tests, but who was perhaps unaware of the conceptual and interpretive richness, and particularly of the distinctiveness, of the five personality assessment traditions just considered. Assuming that she persevered in reading through this highly condensed overview, there are a few "take home" messages that might now be conveyed to her.

First, in Kelly's (1955) terms, the five traditions arose and were developed within different "foci of convenience" and therefore are often most usefully applied within their specific areas of focus. The psychodynamic tradition of Freud arose from the revolutionary idea that the causes and reasons for behavior are frequently not apparent and that we must look "within" the individual, as it were, to discover the sources (often historical) of contemporary problems of living. The personological tradition arose in response to the question of "How shall a psychological life history be written?" The multivariate tradition arose as an extension of the mulifactor assessment of intelligence to the personality domain, and was subsequently concerned with the determination of the basic descriptive dimensions of personality. The empirical tradition arose in the context of descriptive psychiatry, and was originally most concerned with the differential diagnosis of psychopathology. The interpersonal tradition was originally focused on the character and quality of interpersonal relationships and on what persons did to one another within such relationships.

Second, instruments developed or employed within the five traditions have been found to have different "ranges of convenience" (Kelly, 1955), that is, to be generally or specifically applicable to a particular spectrum of assessment problems. Here it must be reiterated that there is not a one-to-one relation between instruments and traditions in this respect. A few examples must suffice: The Rorschach test may be useful in assessing cognitive and perceptual deficits; the WAIS may be useful in detecting covert motivational conflicts; the MMPI item pool has proven a fruitful source for the construction of literally hundreds of scales serving different assessment purposes; the TAT, and its associated need-press framework, has proven useful within many different traditions, as has the NEO PI-R, and the IAS.

Finally, our hypothetical clinician should be aware of the armamentarium of conceptual orientations and instruments that may be brought to bear on a specific referral or assessment task. It is extremely unlikely that there is one test, or one orientation, that will be optimal for all assessment tasks. Practical limitations, especially managed care in the USA, often preclude the once-favored idea of a "standard battery" of tests. It would also not be fair to expect our hypothetical clinician to master all available orientations and tests. But perhaps she could become familiar with a few more. Attending a workshop or two (outside of her present area of expertise) might enhance the professional life of our hypothetical clinician.

ACKNOWLEDGMENTS

We would like to express our indebtedness to Yossef S. Ben-Porath, Sidney J. Blatt, Dan P. McAdams, David S. Nichols, and William McKinley Runyan for their helpful suggestions concerning earlier drafts of sections within their own areas of expertise. However, we accept full responsibility for any errors of fact or interpretation that remain in the present version.

4.13.1 ISSUES IN OBJECTIVE MULTIDIMENSIONAL MULTISOURCE ASSESSMENT

4.13.1.1 Overview

The use of objective questionnaires in the clinical assessment of child and adolescent adjustment continues to grow in popularity. The five years that followed my last review of objective assessment of children and adolescents (Lachar, 1993), have brought additional psychometric advances in instrument development and application. The importance of objective measures in current practice has also been demonstrated by the relative coverage provided in monographs and textbooks available for graduate education and continuing education (Kamphaus & Frick (1996) is an excellent example that supports this observation).

It is also important to consider the effect recent changes in the provision of health care may have upon the use of psychological testing in the diagnostic process. Managed care may influence the use of objective assessment in two quite different ways. First, in the pursuit of cost containment, the use of time-intensive individually administered psychological tests is less likely to be authorized in the routine evaluation of youth, quite independently of the documented value of such procedures. Relatively inexpensive diagnostic questionnaires, in contrast, are more likely to be accepted as a routine component of initial evaluations because they improve upon the efficiency of the intake data collection process. Second, these families of multidimensional measures can contribute substantial value to the program evaluation aspects of managed care. Objective questionnaires have the potential to independently document both the need for treatment as well as to quantify treatment efficacy through repeated application.

This chapter will expand upon many of the themes presented in Lachar (1993) and will describe in some detail four "families" of assessment instruments that meet current standards for intake assessment and treatment evaluation. These materials: (i) assess multiple dimensions of problem behavior, (ii) collect observations from parents, teachers, and youth, and (iii) provide standard scores based upon contemporary national samples. In 1993 only one set of measures met these criteria (Achenbach, 1992); at the conclusion of 1997 four sets of such scales were either commercially available or in press.

4.13.1.2 Multidimensional Measurement

Multidimensional instruments require standardized responses to similarly formatted descriptive statements which generate estimates of a variety of dimensions of child behavior or psychopathology. These estimates are usually visually displayed in the form of a profile of standard scores. These standard scores represent a common metric that has been derived from one normative reference sample or overlapping or similar samples, and are therefore directly comparable (vs. the case of scores from several single-dimension measures that have been standardized on normative samples collected in very different places and times, as well as under different conditions).

Advances in psychopathology and measurement technology demonstrate the clinical advantage of multidimensional measurement. It is the case, rather than the exception, in clinical assessment that several scaled dimensions of adjustment, such as depression and anxiety or inattention and noncompliance, are concurrently elevated in the clinical range. Not only are these dimensions—often classified into externalizing (behavioral excess) or internalizing (behavioral deficit) dimensions—problematic concurrently, the externalizing and internalizing diagnoses are often found to be comorbid. For example, adolescents hospitalized on a psychiatric unit are often described by more than one diagnosis or by a diagnosis that reflects different dimensions of psychopathology. It is not unusual for such adolescents to demonstrate significant levels of depression or anxiety and at the same time demonstrate pathologies of behavioral excess (oppositional defiant disorder, conduct disorder, attention deficit hyperactivity disorder (ADHD); see, for example, O'Connor, McGuire, Reiss, Hetherington, & Plomin, 1998). The most useful assessment procedure will provide a quantified estimate of the pattern of problems in need of remediation and answer relevant questions such as the role that family conflict may play in symptom development or maintenance, and the context of such symptoms.

Multidimensional assessment is uniquely designed to describe patterns of adjustment characterized by dimensions of both poor adjustment and relatively symptom-free adjustment. In many cases the documented absence of certain problems is as important as is the documented presence of others. The following common clinical challenge documents the importance of multidimensional assessment. Children and adolescents are often referred for evaluation by parents, educators, physicians, and mental health professionals because they have been observed to be hyperactive and/or inattentive. Exclusive application of homogeneous measures of ADHD or hyperactivity in such cases can only prove to be problematic. These referred children are often found to be "inattentive" for reasons other than ADHD (depression, anxiety, situational adjustment, learning disability, acquired cognitive disability, etc.). When significant elevation is not obtained on focused hyperactivity scales, guidance in the search for likely alternative diagnoses is not provided. On the other hand, youth found to meet all of the criteria of ADHD often present with coexisting conditions (see, for example, August, Realmuto, MacDonald, Nugent, & Crosby, 1996; Vaughn, Riccio, Hynd, & Hall, 1997). When such comorbid conditions remain unrecognized, their presence cannot be considered in treatment planning. In such cases, the resulting treatment may be compromised by the absence of such information.

4.13.1.3 Multisource Assessment

Although the evaluation of adjustment or psychopathology in adults usually relies on self-report, such self-description is rarely adequate in the evaluation of children and adolescents. Indeed, the context of assessment is fundamentally different for children and adolescents who are unlikely to refer themselves for evaluation or treatment and may not possess the academic, cognitive, or motivational status to complete a comprehensive self-report instrument. The first consideration in this regard is that young elementary school children, perhaps students in K through 3, may be unable to describe themselves adequately through response to questionnaire statements. These children are unlikely to have mastered the range of vocabulary necessary to adequately describe dimensions of adjustment; such language competence is not usually attained before the fourth or fifth grade.

Another consideration is the reality that youth are most often referred for evaluation because they are either noncompliant with the requests of the significant adults in their lives or exhibit problems in academic achievement, often presenting with inadequate reading skills. It is therefore not unusual that completion of a self-report inventory of several hundred items by a high school student (e.g., the Minnesota Multiphasic Personality Inventory-Adolescent consisting of 478 statements) could present quite an assessment challenge.

Parents and teachers not only refer youth for assessment, they are also the primary sources of useful systematic observation. Certainly adults should be the ideal informants to report noncompliance of a child to their requests. Parents are the only consistently available source for report of early childhood development and description of child behavior in the home. Teachers offer the most accurate observations of the age-appropriateness of a child's adjustment in the classroom and academic achievement, as well as of the attentional, motivational, and social phenomena unique to the classroom and to the school. It is likely, however, that such observational accuracy decreases after the elementary school grades, as teachers have very little continuous observation of students who appear for only 45 minutes a day in a classroom of 30 or more other students. (An exception perhaps would be the ratings of counselors, resource room teachers who work with small groups of students, and teachers in self-contained special education classrooms.) Youth self-description, regardless of problems that have been documented for this source of information (Greenbaum, Dedrick, Prange, & Friedman, 1994; Jensen et al., 1996), still must be seen as the most direct and accurate expression of personal thoughts and feelings. (Note that Michael & Merrell (1998) have demonstrated adequate short-term temporal stability for the self-report of third to fifth graders.)

The availability of a coordinated "family of instruments" in which uniquely designed questionnaires are completed by two or three different informant sources, each providing independent sets of child descriptions, offers a natural opportunity for critical comparison of the value of these sources of information. Achenbach, McConaughy, and Howell (1987) conducted a comprehensive literature review and found, although relatively greater between-source agreement was obtained for scales representing externalizing behaviors, very limited concordance in general between the report of parent, teacher, and youth. A review of similar studies that evaluated the responses to objective interviews from parent and child concluded that greater agreement was obtained for visible behaviors and for child–parent pairs with increasing child age (Lachar & Gruber, 1993).

Although one reasonable approach to the interpretation of differences between parent, teacher, and youth is to assign such differences to situation-specific variation (e.g., the child is actually oppositional at home, not in the classroom), other explanations are equally plausable. One alternative explanation of cross-informant variance requires a close examination of the measures being applied. It is a frequent occurrence to find that scales with similar names contain significantly different content. In this situation an apparent lack of agreement between informants on similarly named scales (such as "depression") may more accurately reflect the differences in statement manifest content. At one extreme a clinician might consider accepting any evidence of symptom presence from any informant source, at the other extreme it would also be possible to focus exclusively on problems demonstrated by at least two or even all three informant sources.

On the other hand, the development and application of valid identical across-source measures may not provide optimal assessment data. Such an approach may restrict the diagnostic potential of each informant source by excluding the measurement of attributes that may be uniquely obtained from only one informant source (e.g., a parent-completed measure of developmental delay, a teacher-completed measure of academic skills, or a youth-completed measure of achievement motivation).

Another explanation for poor cross-informant agreement for data gathered in a clinical context acknowledges the potential effect of response sets on the accuracy of such information. Starting with the child or adolescent being assessed, adequate compliance with questionnaire instructions may not be obtained—reflecting either inadequate language or reading skills, or lack of adequate motivation for the task. It is also likely that a youth may not want to share a personal history of maladaptive behavior and current internal discomfort with mental health professionals, although a negative presentation of parent adjustment and home conflict may be more readily provided. At times, youth may also be motivated to admit to problems and symptoms that are not present. These same motivations and conditions may also influence parent report. Indeed, there has been some concern that poor parent adjustment may compromise the validity of parent report (Achenbach, 1981). However, a subsequent review (Richters, 1992) and the specific analysis of this issue with the Personality Inventory for Children (PIC) (Lachar, Kline, & Gdowski, 1987) have found no empirical support for this consideration. Some instruments, however, incorporate validity scales to identify such response sets. These scales are designed to measure random or inadequate responses to scale statements, defensive denial of existing problems, as well as admission of symptoms that are unlikely to be present or exaggeration of actual problems. (Examples of the effect of informant defensiveness on profile pairs are presented in Table 5 and discussed in associated text for the Personality Inventory for Youth (PIY) and the Personality Inventory for Children, 2nd Edition (PIC-2). See also Lachar, in press.)

For the clinician there is a distinct pragmatic advantage in using an assessment system with comparable parent, teacher, and youth versions. Research may document one day that one source of descriptive report is superior to another in the assessment of a specific problem domain (only surveys of the opinions of clinicians and parents are currently available: Loeber, Green, & Lahey, 1990; Phares, 1997). Until that day, however, conditions regularly occur in the conduct of psychological evaluations that on some occasions make it necessary to collect one, and on other occasions another, of these parent-, teacher-, and youth-report questionnaires. Children may be too young, uncooperative, or language-impaired to complete a questionnaire. The evaluation may occur during the summer vacation, or the youth may have not consistently attended one school, or may have left school permanently, making collection of a teacher rating difficult or impossible. Parents may fail family appointments when their child is hospitalized, or children may be under agency guardianship rather than parent supervision. In such not infrequent cases, a "family" of objective questionnaires separately normed for parents, teachers, and youth provide the flexibility to facilitate the collection of data from the source or sources that are available.

4.13.1.4 Psychometric and Technical Considerations

The topics discussed in this section are unlikely to spark much enthusiasm in clinicians who also demonstrate little interest in reading the technical sections of test manuals. These issues, however, are important as they influence test validity and ease of interpretation and must be considered in the selection of instruments for specific clinical applications.

4.13.1.4.1 Scale stability and homogeneity

It may seem quite reasonable to apply the technical standards and statistical techniques first developed in the construction of ability and achievement measures to scales of adjustment and personality. For example, in the development of an age-normed measure of verbal IQ or a grade-normed measure of arithmetic calculation skill, certain assumptions are made. As each of these measures would be conceptualized as relatively homogenous and stable over at least weeks or months, item components would need to demonstrate substantial intercorrelation as well as little change over time (coefficent alphas and test–retest correlations of one week/three months of at least 0.80).

Measures of adjustment or psychopathology, in contrast, can vary in degree of homogeneity and may in fact in some cases be expected to be relatively unstable over time or sensitive to the effects of treatment. A measure of trait adjustment might consist of responses that describe previous behaviors and therefore demonstrate considerable temporal stability, while a measure of mood that consists of self-statements made in the present tense may provide a state measure that is expected to vary considerably over time. An empirically constructed scale in which items have been selected because they have statistically separated well-defined samples (e.g., normal adolescents vs. adolescents adjudicated delinquent) is likely to be multidimensional and limited in homogeneity. In contrast, a scale constructed by factor analysis consists of items that correlate highly with each other and such scales demonstrate substantial homogeneity. The importance of scale homogeneity as measured by coefficient alpha and scale stability represented by the test–retest correlation must be evaluated in light of the expressed meaning and application of each measure. Of importance in any case is the demonstrated validity of these scales; that is, evidence that each scale measures what it is supposed to and that interpretive guidelines are derived from empirically based relationships between scale values and independent observations.

4.13.1.4.2 Scale construction methods and scale character

It is important to be aware of both scale content and scale performance when applying scale standard scores in clinical assessment. Scale content has gained in judged importance and scale items have been selected frequently because of specific content or written to measure specific dimensions (see, for example, the Conners *DSM-IV* scales (Conners, 1997) and the Disruptive Behavior *DSM-IV* scales of the Student Behavior Survey (Lachar, Kline, Wingenfeld, & Gruber, 1999; Pisecco, Lachar, Gallen, Gruber, & Huzinec, 1998). This recent focus on item content is in sharp contrast to previously developed empirically keyed scales in which item performance took preference over item content. Current consensus is that scale content is necessary but insufficient to assure scale validity. It is recommended that clinicians first read the items on each scale and examine the content dimensions provided as well as the content equivalence for parent, teacher, and youth questionnaires before attempting any clinical application.

It is of course generally true that increased scale length will improve the depth or variety of expressed content. Against this reality must be balanced concerns about the time required of informants to complete a questionnaire, an issue that appears to be significant to psychologists who work in test development and those who work in test application. One must also consider the context in which evaluations are to be conducted. A baseline or initial evaluation would justify a more comprehensive evaluation than would a repeated evaluation or some approach to treatment evaluation in which daily or weekly observations are required.

Each clinician will need to judge the value of the information obtained vs. the time needed to generate these measures. In this author's experience, within a clinical (vs. research) context, parents view these questionnaires as appropriate and appreciate such an offer to make this sort of contribution to the diagnostic process. Teachers, unless asked to complete lengthy forms on a whole classroom of students, are quite willing to spend 15 or 20 minutes completing a form that either initiates a referral to a school psychologist or provides necessary classroom observation for an independent or agency-conducted evaluation. The instruments of the families of questionnaires presented in this chapter vary in length from a "short form" of 10 items that generates one standard score to a "short form" of eight 12-item shortened scales that is as long as the full-length versions of some other questionnaires.

Scale length (number of items) and rate of item endorsement (infrequently endorsed items in short scales) within normative and clinical samples directly influence scale performance, such as range of standard scores and the shape of score distributions. Response format is also relevant in that a scale score increment of one point may represent the endorsement of one additional symptom or characteristic (true/false; present/absent) or a subjective increase in symptom observed certainty or frequency (somewhat true to very true; sometimes true to often true). It may be useful to identify the minimum descriptive content necessary to generate a clinically significant standard score. It may also be useful to determine the amount of response difference necessary to move a scale value from normal limits to the clinical range. Note that a scale with a 0–18 raw score range can be generated from either six symptoms rated from 0 to 3, or from 18 true/false statements that vary in both symptom intensity and frequency. Although it will take longer to respond to 18 than to six items, it is obvious that the content basis for standard scores will vary substantially for these two measures. A comprehensive evaluation of any dimension is likely to require more than a handful of observations.

Although these scale scores are usually positively skewed (symptoms and dimensions of psychopathology are not normally distributed), scale distribution may be excessively restricted due to scale length, item response frequency, or normative sample character so that the scale mean and standard deviation that generate standard scores are very limited. (See Rowe & Rowe (1997) for a contemporary discussion of this issue with a focus on the Conners' Global Index.) For example, a scale with a normative mean of 1.13 and a standard deviation of 2.78 (Conners' Teacher Rating Scale-Revised (CTRS-R): Oppositional, female 12–14 years) would generate the following raw to T-score conversions: $0 = 46T$, $1 = 50T$, $2 = 53T$, $3 = 57T$, $4 = 60T$, $5 = 64T$, $6 = 69T$. Because the Oppositional scale consists of six items rated from 0 (not true at all/never, seldom) to 3 (very much true/very often, very frequent), the following interpretive issues are suggested. Considering that the scale raw scores for Oppositional can range from 0 to 18, responses of "not true" or "just a little true" predominate in the normative sample. Only a scale score of "0" extends below the mean. Of most interest, a clinically elevated score ($> 65T$) can be obtained by responding "just a little true" to each item, or "very much true" to only two statements. Please note that other CTRS-R scales actually obtain mean raw scores below 1.0 and standard deviations below 2.0, but the CTRS-R is far from the only questionnaire to exhibit these troublesome psychometric characteristics. Users are well advised to review a test's raw score-to-T score translation table or profile where the issue can be evaluated.

4.13.1.4.3 Evidence of scale and questionnaire validity

All too often test evaluations and reviews discuss internal consistency and reliability at length and then give short shrift to test validity. This is perhaps understandable in that it is easier to make comparisons and establish numerical guidelines for evaluating these characteristics. Unfortunately—and particularly so for instruments rating psychopathology or other infrequent behavior—the emphasis should be quite the opposite. Validity is far more difficult to define, measure, and establish, but it really is the only bottom line. Even a scale that demonstrates somewhat weak or even impaired reliability can be extremely valuable clinically if it can successfully identify a rare or transient characteristic such as violent labile aggression. It is necessary to establish the validity of specific applications of each scale before it can be interpreted with certainty. It should be understood that standard scores derived from the most representative and comprehensive of normative data simply provide the frequency or infrequency of a given score in this normative sample. Just because a pattern of scale standard scores is infrequent does not necessarily demonstrate that this pattern is clinically meaningful or significant. It is also important to acknowledge that scale validity is not a general attribute. The validity of a scale can only be demonstrated within a specific context for a specific purpose.

The construction or selection of a normative sample for each questionnaire is also a process requiring critical review—especially when questionnaires provide a variety of normative options (see, for example, Reynolds & Kamphaus, 1992). In the evaluation of school-aged children, scale raw scores may be converted to standard scores based upon normative (not receiving counseling or special education services), representative (incorporated an accurate proportion of all children), or referred (clinical or special education) samples. Normative samples also differ as to whether they are gender specific or combine the protocols of both boys and girls. It should also be noted that normative samples may be constructed to reflect child age. Such age-referenced samples may represent broadly defined groups such as preadolescent/adolescent, or provide norms that reflect a much more narrow age range (see Conners, 1997). The relative utility of any normative sample rests upon the demonstration that derived standard scores are comparable in validity. For example, the scales of the PIC have been found to be equivalent in their ability to predict external criteria for boys vs. girls and for children vs. adolescents (Kline & Lachar, 1992; Kline, Lachar, & Sprague, 1985). Test authors who promote the use of an atypical normative procedure should demonstrate that the resulting interpretive guidelines are as accurate as those obtained by more traditional means. For example, if a questionnaire provides both traditional gender-specific and novel mixed-gender norms, evidence should be provided that mixed-gender norms generate interpretive guidelines which are either more accurate or as accurate as more traditional gender-specific guidelines.

The construction of a new set of scales for a multidimensional inventory or set of inventories must follow a path in which fundamental evidence of validity must first be obtained. If obtained, additional study of more specific and focused evidence of accurate scale performance must be pursued. For example, when items are placed on dimensions on the basis of manifest content, the accuracy of this placement could be demonstrated through item-to-total correlations in which each item will be expected to obtain the greatest correlation with the dimension on which it has been placed. If the scales are constructed to measure adjustment or psychopathology, each scale could then be applied to regular education and special education and/or clinical samples to determine if meaningful separation occurs between these groups for each scale. Here "meaningful" is more than a statistically significant difference, which when samples are large could be so small as to be of no pragmatic value. Scales in this context should demonstrate at least a moderate effect size—generally about one-third of a standard deviation or greater (Cohen, 1988).

Unlike ability tests that gain initial construct validity by correlation with similar although established measures, scales of adjustment are less likely to demonstrate comparable concordance (0.70s–0.80s) because of differences in content and format. Indeed, substantial correlations obtained between pairs of scales from different tests completed by the same informant most likely reflect substantial shared item content. Adjustment scales for children and adolescents acquire validity through demonstration of external correlates that may take a variety of forms including independent ratings, special education placement, diagnoses, or specific treatment. For example, in students referred for evaluation, elevation of a parent-completed attention deficit hyperactivity scale should correlate with content-congruent teacher ratings, and students diagnosed with ADHD and assigned to receive stimulant therapy should obtain clinically elevated scale scores that subsequently fall within the normative range following successful treatment.

The accumulation of substantial construct validity and the development of empirically based interpretive guidelines are prerequisite for a questionnaire to achieve status as an established clinical measure. Unfortunately, the accumulation of a substantial bibliography provides an insufficient basis for the development of this status. Tests are far more often applied in the quantification of phenomena under study rather than applied in the study of scale score meaning. For example, contrast "How many children with mild mental retardation also demonstrate the *DSM-IV* criteria for a disruptive behavior disorder?" with "How do children with mild mental retardation who also obtain an elevated parent-informant hyperactivity scale differ in some way from children with mild mental retardation who do not obtain such an elevated scale?" That is, tests of adjustment are usually applied in the paradigm in which the investigator asks the question "What is the likelihood of a given test result given certain clinical criteria?" vs. "What is the likelihood of certain clinical phenomena given a certain test score, score range, or score pattern?" It is the latter question (and associated research design) that replicates the use of tests in clinical assessment and hence offers the better evidence of validity.

The clinician who reads that 95% of a sample of adolescents hospitalized on a psychiatric unit with a discharge diagnosis of major depression obtain an elevated score on a certain depression scale should understand that this information is insufficient to demonstrate either construct validity or provide an interpretive guideline. If, for example, a comparable proportion of the remaining adolescents on that psychiatric unit also received similar test results, these additional data would suggest that this "depression" scale measures general distress rather than depression. In addition, clinicians should pay attention to any evidence of a scale's ability to make clinically meaningful distinctions, not the separation of normal and referred subjects (see, for example, Forbes (1985) in which PIC profiles of children with the diagnosis of ADHD were compared to the PIC profiles of behaviorally disturbed children whose symptom presentation did not support such a diagnosis). It is also important to focus on studies that document the independent correlates of scale elevations or profile patterns (see, for example, LaCombe, Kline, Lachar, Butkus, & Hillman (1991) and the clinician, teacher, and self-report correlates of parent-report PIC-2 shortened scales presented in Table 4). In general, such studies assemble a sizable data set that includes both the test scores under study and other clinically meaningful independent information, with the goal of determining the degree to which test variables accurately predict clinically meaningful variables across all subjects. In this way a scale's convergent validity (scale elevation for patients afflicted with the problem to which the scale is directed) and discriminant validity (scale nonelevation for nonafflicted subjects or patients afflicted with unrelated problems) (Campbell & Fiske, 1959) are established.

4.13.2 MULTIDIMENSIONAL MULTISOURCE RATING SCALES

4.13.2.1 Overview

The second section of this chapter describes the four families of commercially available multidimensional, multisource questionnaires. Although considerable detail is provided for each set of scales, clinicians are urged to review all materials that may be appropriate for their specific applications. The conduct of this review has been difficult. Within these four sets of scales, one (Behavior Assessment System for Children; Reynolds & Kamphaus, 1992) was first published in 1992, two (Child Behavior Checklist and related measures: Achenbach, 1991; Conners Rating Scales (CRS): Conners, 1997) have recently been revised and expanded, while the fourth set of scales includes one recently published questionnaire (Personality Inventory for Youth: Lachar & Gruber, 1995), one questionnaire just revised (Personality Inventory for Children, 2nd Edition (PIC-2): Lachar, 1999), and one new measure (Student Behavior Survey (SBS): Lachar, Kline, Wingenfeld, & Gruber, 1999). Although the established materials have been collectively applied in approximately 3000 studies, no systematic review has been conducted to identify those studies that could form the basis for the development of interpretive guidelines (note in contrast the actuarial studies of profile scales and profile types for the PIC: Lachar & Kline, 1994).

4.13.2.2 Conners' Rating Scales-Revised

[Multi-Health Systems Inc., 908 Niagara Falls Boulevard, North Tonawanda, NY 14120-2060, USA]

The Conners scales were derived from teacher and parent measures first used in research conducted during the 1960s in the study of the pharmacological treatment of disruptive behaviors. The Conners' Rating Scale-Revised (CRS-R) emerged from a considerable research base generated over more than 30 years. An annotated bibliography of over 450 studies is available from the publisher (Wainwright & MHS Staff, 1996). Parent, teacher, and adolescent response to questionnaire items takes the same four-choice options: 0 = Not True at All (Never, Seldom), 1 = Just a Little True (Occasionally), 2 = Pretty Much True (Often, Quite a Bit), and 3 = Very Much True (Very Often, Very Frequent). CRS-R standard scores are linear *T* scores derived from contiguous three-year segments of the normative sample. The CRS-R hand scoring forms are easily completed and scored, and computer support for scoring and interpretation is available. The 1997 manual (Conners, 1997) and most current review chapter (Conners, in press) suggest that these scales continue to focus on ADHD and strengthen their assessment of related or comorbid disorders.

Conners in these publications emphasizes the relative importance of teacher observation in making these diagnostic determinations and suggests that the comparison of sources (teacher, parent, adolescent) can determine the reliability of the generated diagnostic hypotheses. Conners also suggests that the CRS-R scales should be augmented when their internalizing scales are elevated by using other measures, such as the Children's Depression Inventory (CDI) (Kovacs, 1992) and the Revised Children's Manifest Anxiety Scale (Reynolds & Richmond, 1985).

Conners details his concern for the accuracy of each protocol and the possible effect of response sets, such as defensiveness, although the CRS-R does not provide measures of such response sets. Conners suggests that it is useful to review the within-scale consistency of the content of items rated "3" (very much true/very often, very frequent) within elevated ($>64T$) scales/indices, although the efficiency of this process would be vastly improved through the development of a consistency scale. Although the manual suggests that a clinically elevated scale exceeds 64*T*, case examples present scale elevations below 60*T* as contributing to the diagnostic process. The manual presents and analyzes raw scores (mean, standard deviation) rather that providing *T*-score ranges and *T*-score frequencies within well-defined clinical or special education samples (e.g., establishing the scale *T*-score ranges for the dimensions that best define children diagnosed with ADHD).

4.13.2.2.1 Conners' Parent Rating Scale-Revised

The 80-statement form is the most comprehensive of the Conners' parent measures. Although the manual notes the reading level of this form as ninth grade, Conners' Parent Rating Scale-Revised (CPRS-R) items range in complexity from one-word stems such as "Irritable" to a 28-word descriptive phrase: "Does not follow through on instructions and fails to finish school work, chores or duties in the workplace (not due to oppositional behaviour or failure to understand instructions)." The CPRS-R generates seven factor-derived nonoverlapping scales apparently generated from the ratings of regular education students from the normative sample ages 3–17 years (Oppositional, Cognitive Problems, Hyperactivity, Anxious-Shy, Perfectionism, social problems, and psychosomatic), Conners' ADHD Index, Conners' Global Index, and *DSM-IV* scales Inattentive, Hyperactive-Impulsive, and Total. The ADHD Index consists of the 12 items empirically determined to best identify children at risk for an ADHD diagnosis (this 12-item set varies by informant source across this family of tests). The Conners' Global Index includes the

10 items historically labeled the "Hyperactivity Index" in previous published and unpublished versions of the Conners parent and teacher scales. This index is presented as the best general measure of behavioral adjustment and the one most sensitive to treatment effects.

Three additional forms are derived from these 80 items: (i) a shortened form of 27 items (CPRS-R:S) that generates the 12-statement ADHD Index and shortened forms of the Oppositional, Cognitive Problems, and Hyperactivity scales, (ii) a 26-item format that provides the ADHD Index and the three *DSM-IV* scales (CADS-P), and (iii) a sheet that only presents the 10-item Global Index. These three shortened forms are provided as options to monitor treatment effects.

Table 1 presents the pattern of scale and Index overlap (scales: Oppositional, 10 items; Anxious-Shy, 8 items; Perfectionism, 7 items; Social Problems, 5 items; and Psychosomatic, 6 items are each formed from unique items).

The *DSM-IV* Hyperactive–Impulsive and Hyperactivity scales exhibit considerable overlap as do the *DSM-IV* Inattentive and Cognitive Problems scales, suggesting the need for additional guidelines for application and interpretation of the full-length and shortened parent and teacher scales. It is also interesting to note that the Global Index, presented as the 10 items most sensitive to behavioral disturbance, almost never appears on any other scales (eight out of 10 items are unique).

4.13.2.2.2 Conners' Teacher Rating Scale-Revised

The full-length version of the Conners' Teacher Rating Scale-Revised (CTRS-R) consists of 59 items. Across-informant analysis may be facilitated in that the six CTRS-R factor-derived scales from three- to 17-year old normative children have been given the same names as the CPRS-R scales (there is not a teacher version of the CPRS-R Psychosomatic scale). The Conners' Global Index, Conners' ADHD Index, and three *DSM-IV* scales of the CPRS-R are also incorporated in this form. Three short teacher forms are also available: (i) a 28-item version that provides shortened Oppositional and Cognitive Problems scales, the Hyperactivity scale, and the ADHD Index, (ii) a 27-item version that provides the 12-item ADHD Index and the three *DSM-IV* scales, and (iii) a single sheet that presents the 10-item Global Index.

A comparison of CPRS-R and CTRS-R scales and index item content and scale length may shed some light on CRS-R construction and suggest issues in clinical application. Because the CTRS-R is shorter (59 items) than the CPRS-R (80 items), CTRS-R factor-derived scales are also shorter, with individual responses contributing greater to score derivation. The greatest shortening is present on factor scales Oppositional (10 to six items) and Cognitive Problems (12 to eight items). Assignment of identical titles to CPRS-R and CTRS-R scales should not lead the clinician necessarily to assume comparable item content for parent–teacher scale pairs. While the Global Index and *DSM-IV* scales do consist of items with identical or comparable content, the remaining CTRS-R score dimensions, except for the Cognitive Problems and Hyperactivity scales, consist of no more than 50% comparable content for similarly titled CPRS-R dimensions (six of the eight CTRS Cognitive Problems items have equivalents on the identically named 12-item CPRS dimension. Six of the seven CTRS Hyperactivity items have equivalents on the identically named nine-item CPRS dimension). Therefore, it was not unexpected to observe that the greatest parent–teacher agreement for normative cases occurred on the Global Index and *DSM-IV* measures (Connors, 1997, p. 126).

4.13.2.2.3 Conners–Wells' Adolescent Self-Report Scale

This 87-item questionnaire has been designed for students ages 12–17 with at least a sixth grade reading competence. Conner–Wells'

Table 1 CPRS-R item overlap.

Measure (no. of items/no. of unique items)	*B*	*C*	*H*	*K*	*L*	*M*
B:Cognitive problems (12/6)			3		5	
C:Hyperactivity (9/3)				1		5
H:Conners' ADHD Index (12/6)	3			1	2	2
K:Conners' Global Index (10/8)		1	1			
L:*DSM-IV* Inattentive (9/4)	5		2			
M:*DSM-IV* Hyperactive-Impulsive (9/2)		5	2			

Adolescent Self-Report Scale (CASS) includes six nonoverlaping factor-derived scales with lengths of either eight terms (Anger Control Problems; Hyperactivity) or 12 items (Family Problems; Emotional Problems, Conduct Problems, Cognitive Problems). This form can also be scored for a 12-item ADHD Index and two *DSM-IV* ADHD scales (as in the parent and teacher versions). Two shortened versions are available. In one, 27 items yield shortened versions of three factor-derived scales (Conduct Problems, Cognitive Problems, and Hyperactivity) and the 12-item ADHD Index, while the other provides the ADHD Index and the two *DSM-IV* scales Inattentive and Hyperactive-Impulsive in 30 items.

Comparison of item content between adolescent and parent report demonstrates excellent concordance for *DSM-IV* scales. Although reasonable agreement would be expected to be found for ADHD Indexes, Cognitive Problems and Hyperactivity scales, and between CPRS-S Oppositional and CASS Anger Control Problems, very few items from the parent scale can be identified in the self-report version.

4.13.2.2.4 Commentary

Table 2 displays average *T*-score group estimates derived from mean raw scores for parent, teacher, and self-report scales from three samples: general clinical, ADHD, and matched normative (Conners, 1997, pp. 135–136).

It would be very useful for the CRS-R Manual to provide for each sample the proportion of scale scores that equaled or exceeded the minimum *T*-score for the clinical range, whether this is 60*T* or 65*T*. Such lack of clinically relevant information is also demonstrated in a journal presentation of the six factor-derived CASS scales (Conners et al., 1997). In comparing 86 adolescents with a sole diagnosis of ADHD combined type to matched normative controls, an overall correct classification rate of 82.6% was obtained using all six scales. Although all six scales were statistically significant in group contrasts (demonstrating comorbidity and need for multidimensional assessment), no indication of the relative importance of each scale's contribution to this discrimination is given, nor are the proportion of elevated scores per scale provided for ADHD and contrast samples.

Table 2 documents substantial normative/clinical differences as well as the relative superiority of parent report when it is compared to the companion self-report form. Brevity and ease of application would recommend the CRS-R measures in monitoring the treatment of children with ADHD. Versions of *DSM-IV* scales for parent, teacher, and youth will allow the study of the accuracy of each informant source in diagnosing ADHD as well as the study of across-informant agreement.

The majority of CRS-R measures appear to have been developed out of distinctly different item pools, resulting in sets of scales that may complement rather than duplicate each other. It would be useful for the manual to explain why the CRS norms incorporate three-year intervals. The current profiles suggest in displayed raw-to-*T*-score conversion substantial and variable gender and age effects. The magnitude of this age effect is easily demonstrated by tracking on a profile the *T*-score equivalents for one scale raw score across the five sets of age norms. For example, a *DSM-IV* Hyperactive Impulsive raw score of 12 for males resulted in the following five *T* scores: 3–5, 60*T*; 6–8, 63*T*; 9–11, 66*T*; 12–14, 70*T*; 15–17, 81*T*. In contrast, the ADHD Index demonstrated far less age-related variation.

4.13.2.3 Child Behavior Checklist/4–18 and 1991 Profile (CBCL); Teacher's Report Form and 1991 Profile (TRF); Youth Self-report and 1991 Profile (YSR)

[University Associates in Psychiatry, 1 South Prospect Street, Burlington, VT 05401-3456, USA]

The CBCL, the first published measure of these three (other forms now cover preschool, direct observation, and young adults), was initially published in 1983 as a direct extension of the factor analytic study of child problems and symptoms first published in 1966 (Achenbach, 1966). The 1983 CBCL consisted of two parts, an assessment of competence and a series of factor-derived behavior problem scales constructed from 120 brief descriptions. Each checklist item is rated by a parent as either 0 = Not True (as far as you know), 1 = Somewhat or Sometimes True, or 2 = Very True or Often True, with several items requiring individual elaboration when these items are positively endorsed (scores of 1 or 2). Because of these 17–21 items in each checklist, the informant must be closely monitored and an experienced clinician must review these comments before each pamphlet is submitted to more automatic scoring procedures (Drotar, Stein, & Perrin, 1995). A companion teacher rating form became available in 1986 and a self-report checklist was published in 1987. These forms and subsequent revisions have been used in over 2000 citations (Vignoe & Achenbach, 1997). The popularity of the CBCL and related instruments in research application has had a significant influence on the study of child and adolescent psychopathology since 1986.

Table 2 Average approximate *T*-scores for ADHD, clinical (CLIN), and normative (NORM) samples.

	ADHD	*CLIN*	*NORM*
CPRS-R			
Oppositional	59	63	47
Cognitive Problems	67	57	46
Hyperactivity	69	58	48
Anxious-Shy	56	58	49
Perfectionistic	49	57	50
Social Problems	63	68	48
Psychosomatic	56	57	48
Global Index	67	64	46
ADHD Index	66	59	47
DSM-IV Total	69	59	47
CTRS-R			
Oppositional	61	64	47
Cognitive Problems	56	50	47
Hyperactivity	69	68	49
Anxious-Shy	62	62	46
Perfectionistic	56	62	49
Social Problems	51	58	53
Global Index	66	62	46
ADHD Index	65	58	48
DSM-IV Total	64	58	46
CASS			
Family Problems	53	53	46
Emotional Problems	56	56	47
Conduct Problems	57	54	45
Cognitive Problems	60	56	44
Anger Control Problems	57	57	47
Hyperactivity	57	52	45
ADHD Index	59	53	44

In each of these three forms competence has been measured through rationally developed scales that vary by informant source. The factor-derived dimensions of child problems and symptoms followed a similar general structure for each informant source (each designated an "axis" by Achenbach). Each form's profile recorded several narrow-band scales (designated "syndromes" by Achenbach), summative Internalizing and Externalizing scales derived from second-order factor analysis, and a Total Symptoms scale. A series of item analyses (principal components analysis followed by varimax rotation) was applied to independent clinical samples of boys or girls within several age-range defined samples, resulting in dimensions often unique for one gender or one age group, as well as scales with the same titles but differing in content. The products of what appears to be a direct (vs. guided) unreplicated application of a data reduction technique of scale construction proved to be problematic. These item analyses apparently identified at times either sample-specific or age-/gender-specific variance rather than broadly demonstrable dimensions. For example, only the profile for 12–16-year-old boys did not include a depression dimension. (Certainly this result could not be taken as support for the conclusion that adolescent boys do not demonstrate problematic depression!) Obvious problems presented themselves in applying these scales in research and clinical assessment. Repeated administration to the individual case over time could result in changes in scores as likely to be related to instrument or normative variation as to actual changes in subject status.

The 1991 revision, documented in five monographs totaling over 1000 pages, represented a major departure (Achenbach, 1991a, 1991b, 1991c, 1991d, 1993). This revision, in contrast to the earlier versions of these checklists, emphasized consistencies in scale dimensions and scale content across child age (4–18 years), gender, and respondent/setting. Because the actual checklist items remained essentially the same, this revision also provides substantial continuity, allowing either the continued use of the original sex-age-specific narrow-band scales, or the rescoring of previously obtained protocols to generate the new scales. (Readers may find it useful to first read Chapter 3 of Achenbach (1993) to gain an overall appreciation of these checklists.)

Of primary importance is that a series of within-instrument item analyses was conducted to obtain dimensions common across gender and age groups ("core syndromes"). Substantial samples of protocols from each form obtained from clinical and special education settings were evaluated (4455 CBCLs, 2815 TRFs, and 1272 YSRs). This current version also provides eight narrow-band scales for each informant derived from analysis of the 89 items common to parent-, teacher-, and self-report forms, as well as Internalizing, Externalizing, and Total Scales. The CBCL Internalizing scale score is derived from the responses of three narrow-band scales: Withdrawn, Somatic Complaints, and Anxious/Depressed. The Externalizing scale score includes the responses from two narrow-band scales: Delinquent Behavior and Aggressive Behavior. Three other common scales were not placed on these two broad-band dimensions: Social Problems, Thought Problems, and Attention Problems. Review of scale content reveals some item overlap across these eight scales within each form, substantial difference in scale length within a profile (e.g., TRF scales range from eight to 25 items), and scales that are identically named yet vary in content across informants. Close examination reveals that only one of these narrow-band scales ("cross-informant syndromes"), Somatic Complaints, presents the same nine items to parent, teacher, and youth.
